THE CONCEPT OF
ALANCED HOSPITAL COMMUNITY

THOMAS McKEOWN

paper I shall consider two firmly rooted fea- our hospital tradition One is the separation of for the chronic and mentally sick from the gen- pitals The other is the concept of hospitals as structures, of more or less uniform design, each of provides a full range of services Both features origin to circumstances which no longer exist, would be considerable advantages in getting them.

separation of hospitals for the chronic and men- sick from the general hospital system is due to the formerly various classes of patients were regarded ent problems The infectious were to be isolated, tally ill were to be locked up, the chronic sick housed with the destitute, who were to be put to and only in the general hospitals was the idea of tion and treatment well established by the begin- the present century There was no conception munity of sick people, differing in age or in the of their illnesses, but with essential medical, nurs- social requirements in common In these cir- nces it was inevitable that the various classes of should be placed in different buildings, often ed by long distances and under different adminis- ns The 20th century has established the principle common standard of care and treatment, and the al Health Service has created a single hospital stration. We have yet to break through the thought which prevents us from realising that, if patients be separated, there is a far more satisfactory basis their age or the distinction between a physical and tal illness

inevitable consequence of the separation was the pt of a hospital as a single building providing a full of services, rather than as a group of buildings pro- complementary services It was necessary to make tals, so far as possible, self-contained In asylums poor-law institutions the standard of care was until tly so low that this requirement had little signi- ce, but in general hospitals it led to an attempt to able within every unit all the most complex resources edicine The general hospital has now become, in people's eyes, the model of what a hospital should nd attempts to improve the mental and chronic-sick tals are based on it.

we ignore the various subdivisions of the general tal system (obstetrics, paediatrics, chest diseases, and), hospital organisation is still based essentially on eparation of the mentally ill, the short-term physic- ll, and the long-term physically ill (identified mainly vanced age) To some extent this division is imposed e separation of existing buildings; but it is so deeply d in the tradition that it is still accepted in future ing It is a concept which has manifest disadvan- of which two are particularly serious It brings the same unit patients who need the full resources modern hospital and others who need only simple ion, or remain in hospital solely for social reasons And so long as they are isolated it seems impossible to staff adequately the mental hospitals and those for the chronic sick Indeed, so obvious are the disadvantages that small psychiatric and geriatric units are now sometimes included in general hospitals But the full implications of the traditional separation have still to be faced

Classification of Hospital Patients According to their Needs

Once it is recognised that the chronic sick should receive the same standard of medical care as the acute sick (or more accurately, since it is the real basis of separation, that older patients should receive the same standard as younger ones), and that patients who are mentally ill need not be separated sharply from those who are physically ill, one must conclude that the type of institution in which a patient is placed should be determined primarily by his needs An assessment of the needs of Birmingham patients in mental and chronic-sick hospitals (Lowe and McKeown 1949, Garratt, Lowe, and McKeown 1958) suggested that they could be divided broadly into four classes

1 Patients who needed full hospital facilities, such as frequent medical attention and skilled nursing

2 Patients who needed only limited hospital facilities—essentially simple nursing (washing, dressing, feeding, attention to bladder and bowel, &c.) without mental supervision.

3 Patients who needed only limited hospital facilities—essentially supervision because of their mental state, with (in a few cases) simple nursing

4. Patients who needed no hospital facilities, but remained in hospital chiefly for social reasons

The table gives the distribution between the four classes of Birmingham residents in mental and chronic-sick hospitals In this table patients in other types of hospital are grouped together on the assumption that they require full hospital care Actually, as was found in sanatoria (Lowe and Geddes 1952), not all of them do, but our data are not sufficient to enable us to say what the proportion is

On this assumption, that full hospital facilities are needed by all patients in general hospitals, the percentages of Birmingham hospital patients in each of the four classes listed above are 54, 9, 31, and 6 respectively Fig 1 shows the present location of these patients, and fig 2 shows the regrouping which would result from bringing together patients with similar needs

I do not, of course, suggest that all the patients in each class have identical needs, within each class there is con-

SUGGESTED REGROUPING OF BIRMINGHAM HOSPITAL PATIENTS ACCORDING TO THE TYPE OF FACILITIES NEEDED FOR THEIR CARE

Suggested regrouping of patients according to facilities needed	Present location of patients			Total	
	Mental* hospitals	Chronic-sick hospitals	General and all other hospitals	No	%
Full hospital care	459	309	4406†	5174	54
Limited hospital care without mental supervision	59	818	—	877	9
Limited hospital care with mental supervision	2596	309	—	2905	31
Hostel only	441	108	—	549	6
Total	3555	1544	4406	9505	100

*Patients in mental-deficiency institutions are excluded.
†It has been assumed that the patients now in general and other hospitals, for whom we have no data, all need full hospital facilities

Fig 1—PRESENT LOCATION OF BIRMINGHAM HOSPITAL PATIENTS

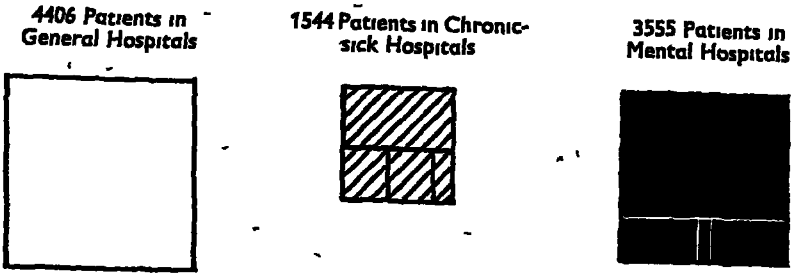

Fig 2—SUGGESTED REGROUPING OF BIRMINGHAM HOSPITAL PATIENTS

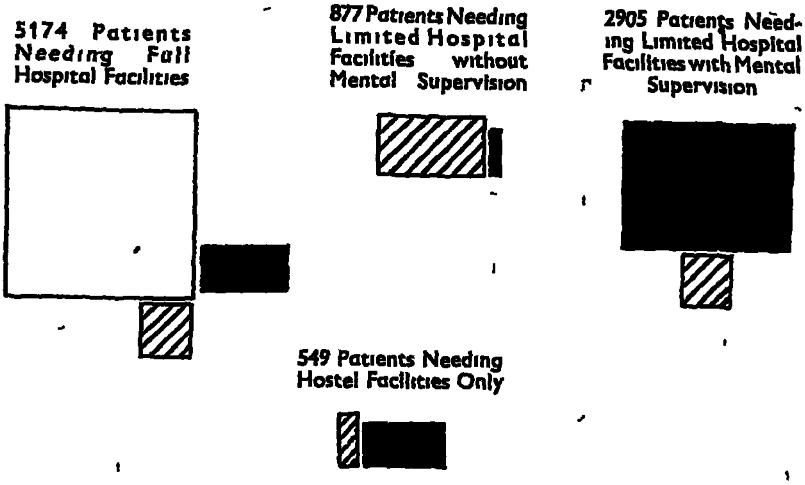

siderable scope for variation in type of accommodation and staff But as regards the facilities to be provided, the division here proposed seems the most fundamental, it brings together patients who, in terms of their hospital needs, have more in common with one another than with those in any other class

Advantages of a Common Site

So far we have been considering a regrouping of the present hospital population in order to bring together patients with similar needs If such a regrouping were effected, the resulting four classes could be accommodated either on different sites or on a common site I shall now consider the advantages of a common site in relation to administration, education, and research

Administration

One of the attractions of the National Health Service is that by creating a single administration it has exposed all types of hospitals to scrutiny according to a standard formerly applied only to general hospitals By this standard the services of mental and chronic-sick hospitals are still grossly deficient, and their deficiencies are not easily remedied The chief difficulty is to provide enough doctors and nurses It is conceivable that in years to come enough doctors may be forthcoming, partly because of increasing interest in psychiatry, and partly because of redundancy in other specialties But the nursing problem is unsolved, and under present arrangements is perhaps insoluble It derives basically from the fact that the nursing services as a whole already draw fairly heavily on the numbers of girls of a reasonable standard of education in the appropriate age-group An effective nursing service will need both a closer adaptation of training to function, on the lines suggested in the Nuffield report (Nuffield Provincial Hospitals Trust 1953), and a more equitable distribution of nurses between the various types of hospital In present circumstances they cann be redistributed, for whereas a doctor who could not find a niche elsewhere might be ready to serve in a mental or chronic-sick hospital, a nurse in the same circumstances would be more likely to leave nursing

So long as the mental and chronic-sick hospitals are separated from the gener hospitals, they must depend on recruitment of nurses and doctors prepared devote themselves exclusively to the services, and the difficulties will remain The difficulties can, I believe, be over come only by placing these hospitals close enough to the general hospitals to make it possible for the same staff to serve both Most doctors and nur would be willing to make a contributio to the care of the mentally ill and th chronic sick if it could be reconcile with their other work, but they will no do so if it obliges them to cut themselve off completely and permanently from their main interests

A second administrative advantage o a common site is that it would provid far greater flexibility in the use o buildings and staff In some specialties need are changing rapidly, and it is almost impossible to say what they will be in ten or twenty years' time For example, it is possible, though hardly certain, that advances in therapy and improved outpatient and domiciliary care will greatly reduce the size of the mental-hospital population

In these circumstances it seems vital that buildings should be so sited that if they are not needed for their original purpose they can readily be converted to other uses This is impossible so long as major sections of medical work are isolated It would be relatively easy if they were all on the same site

Education

To a very considerable extent the decision of doctors and nurses about their future work is determined by wha they see and hear in the hospitals where they are trained Unfortunately patients in teaching hospitals, and in the non-teaching hospitals in which schools of nursing are usually located, are very unrepresentative of the tota hospital population Inevitably students conclude tha the work of general hospitals is the chief interest of doctors and nurses, and that, apart from a few eccentric with a sense of vocation, no-one works in a mental o chronic-sick hospital if he can possibly do anything else This interpretation cannot be altered by token visits to outlying hospitals, which are as likely to harden a determination never to set foot in them again

To recognise this difficulty is not necessarily to question the advisability of basing training on general hospitals, or to suggest that the type of patient admitted should be changed Indeed, if the only way in which the hospital population available for teaching purposes could be made more representative were to admit long-sta mentally ill and chronic-sick patients to the general wards it could well be argued that the disadvantages would outweigh the advantages But the grouping of hospitals with complementary services on a common site is an entirely different proposal patients would be housed in buildings designed after close examination of their needs What is important for teaching is that the student doctor and nurse should see something much nearer to a cross-section of the whole hospital population, in circumstances in which they recognise that all types of patients are equally acceptable as a medical responsibility and interest

Research

Confronted for the first time with the existing arrangements in research, an observer might be excused for concluding that, through some unfortunate error in casting, the ablest workers had been assigned to the easiest problems The reasons for this situation are complex, but certainly one of them is that administrative arrangements determine what the research-worker sees, and what he sees has a considerable bearing on what interests him A physician who admits to his wards only acutely ill people is unlikely to be much concerned with the chronic sick, and a psychiatrist preoccupied with short-term treatment or mendelian inheritance cannot be expected to think constantly about the chronic psychotic Not least of the advantages of having all facets of medical work on a single site is that it would bring some of the thorniest and socially most important problems to the attention of the ablest workers It can hardly be doubted that the slow advance with these problems hitherto has been partly due to their isolation

A Balanced Hospital Community

Having considered the advantages of assembling the various elements of the hospital system on a single site we may now examine some of the implications of such a policy I must first state the proposal as clearly as possible What is suggested is that hospitals should be planned as a group of buildings with a common medical and nursing staff providing complementary services for all classes of patients, rather than as single buildings providing a full range of services for selected groups The buildings would be of varied size, design, and permanence of structure, each closely adapted to the needs of the patients who would occupy them

There can be little doubt that if architects were given the opportunity to apply to such a hospital community the imaginative treatment which has been so successful elsewhere, the results would be equally attractive Ideally the community would not be isolated, at its centre there would be careful siting of buildings and control of traffic, but at its periphery it would merge with the neighbourhood which it served By avoidance of large buildings, and by inclusion of other amenities—shops, amusements, and so on—a domestic rather than an institutional setting could be created In these circumstances the analogue of the hospital would no longer be the somewhat forbidding block of flats, but the well-planned housing estate or university centre

If this proposal is not to be dismissed as romantic and unrealistic, we must consider at least two possible objections One is that the capital and maintenance costs would be excessive The other is that, however attractive such a setting might be to the architect or planner, its amenities would bear little relation to the real needs of the hospital population

It is true, of course, that a considerable capital outlay would be required to establish such a centre But there are several reasons for thinking that in relation to the services provided the costs would be lower than those of the traditional hospitals

(a) There would be no duplication of expensive facilities or mixing of patients with different needs

(b) Three of the four major units (see diagram) could be of cheap construction

(c) Because of the relatively simple conversion of unwanted facilities to alternative use, there would be little waste

The last is a particularly important consideration in a period when numbers and types of patients may change rapidly The trimmings which could contribute so much to the creation of a domestic atmosphere—shops, restaurants, and amusements—could operate on the usual commercial basis, and with a favourable site in relation to a large resident population there is no reason to suppose they would not do so Nor need we suppose that maintenance costs must be excessive

The objection that the amenities would bear little relation to the real needs of hospital patients derives from failure to appreciate the true nature of the whole hospital population For the acutely ill bedfast patient who is retained for a few weeks, the general character of the area in which he is cared for is perhaps of secondary importance But a substantial part of the hospital population is ambulant, and the period of admission is measured in years rather than days It is for these patients that the character of the area and the nature of its general amenities are so important At the very least they would provide a more attractive environment in which to spend a long period, and in the case of the mentally ill it is not too much to expect that they would make a considerable contribution to recovery

Possibilities Where Planning is Restricted by Existing Hospitals

Another possible criticism of the idea of a balanced hospital community is that however desirable it may be, and however practicable in countries such as India or Ghana where the planner can work on a virgin site, it has little bearing on the problems of areas where planning is restricted by existing structures In the British Isles for a long time we shall have to make do with the present hospitals, however unsuitable in design, and many of the available sites, particularly in urban areas, are so small that they could not accommodate a balanced community

Nevertheless, though the transformation of the hospital centre may be slower than we might like, it seems essential to have in our minds a model of what it ought to be in future For while we must accept the limitations imposed by an earlier tradition, we need not increase the difficulties by continuing to build within that tradition Almost every major development within the service would be influenced in some degree by a decision that hospitals should no longer be planned as isolated structures of uniform design In the planning of a general hospital, for example, it would affect both the location and size of the site, and the design of the building itself would be different if it were to accommodate those of the mentally ill and the aged sick who need the full resources of a modern hospital It would be evident that at all costs the isolation of hospitals for the mentally sick and chronic sick should be avoided

Summary

An analysis of the medical and nursing needs of Birmingham hospital patients showed that they could be grouped into four classes, according to whether they required (a) full hospital facilities (54%), (b) limited hospital facilities, consisting of basic nursing without mental supervision (9%), (c) limited hospital facilities, consisting of mental supervision with little basic nursing (31%), and (d) no hospital facilities (6%)

Considerable advantages would result from planning hospitals as a group of buildings with a common medical and nursing staff providing complementary services for all classes of patients, rather than as single buildings providing a full range of services for selected groups

PREVIOUSLY we presented evidence indicating that postoperative wasting of protein and loss of body-weight can be minimised or prevented by giving intravenously a solution containing 5% protein hydrolysate and 10% hexose in conjunction with a fat emulsion or an anabolic hormone (Abbott 1955, Abbott et al 1953, 1955, 1957 a and b, Holden et al 1957, Krieger et al 1957, Levey et al 1957) Since there is still some controversy about the use of these preparations, we have tried to obtain more conclusive data

We believed that the relative importance of nutrition and operative trauma in influencing postoperative metabolism could be estimated by comparing the metabolic response of the patient to the same intravenous regimen during a three-day control period and subsequently during a three-day postoperative period To restore the patients to a nutritional state comparable to that which existed before the control period they were given an adequate oral intake for three or four days before the operation In this manner it should be possible to differentiate the metabolic alterations induced by surgical trauma from the biochemical changes resulting solely from the various nutritional regimens The metabolic alterations were assessed by comparing the changes in weight, along with sodium, potassium, and nitrogen balance and the urinary excretion of 17-hydroxy-corticoids during the three-day control and postoperative periods Moore et al (1955) and Steenburg et al (1956) have stated that there is a correlation between the cumulative nitrogen balance and the urinary 17-hydroxycorticoid output for the first four postoperative days It is also generally believed that there is an obligatory retention of water and sodium and a deficit of potassium postoperatively The validity of these concepts was further investigated

Methods

Eleven women and two men about to undergo an elective cholecystectomy were admitted to the metabolic division of the University Hospitals of Cleveland so that accurate observations could be made These patients were given one of the three following regimens in the three-day control and postoperative periods

Group A —Three women (fig 1) and two men (fig 2) were given only 5% dextrose in water intravenously

Group B —Four women (fig 3) were given only 5% dextrose in water to which had been added about 90 mEq of sodium and 80 mEq of potassium daily

Group C —Four women were given 5% protein hydrolysate in a 10% fructose solution † to which sodium and potassium were added to provide a daily intake of 90 mEq of sodium and 80 mEq of potassium

The intravenous infusions were started between 8 A M and 9 A M and regulated so that the patients received 500 *ml* per hour All excreta were collected and analysed for sodium, potassium, and nitrogen by methods previously described (Abbott et al 1953) The daily urinary excretion of 17-hydroxycorticoids determined by the method of Glenn and Nelson (195 To determine accurately the daily changes in the bo weight the patients were weighed at 6 30 A M voiding and at least eight hours after taking any food or fluids

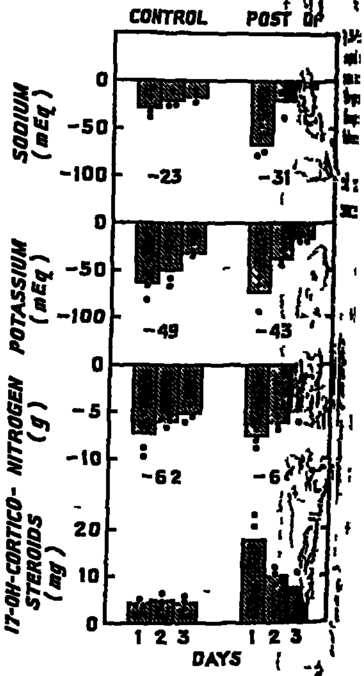

Fig 1—Metabolic balances for sodium (mEq), potassium (mEq), and nitrogen (g) and daily excretion of 17-hydroxycorticoids in 3 female patients receiving 5% dextrose in water during control and postoperative periods

The length of the sodium, potassium, and nitrogen histograms represents average daily balance for 3 patients, and the dots represent the individual daily values for each patient. The numbers below the balance charts represent the average balance in mEq. daily for sodium and potassium and in g daily for nitrogen in the 3 patients during the control and postoperative periods

Results

The data obtained in studying the patients in group (figs 1 and 2) show that the deficits of sodium, potassium,

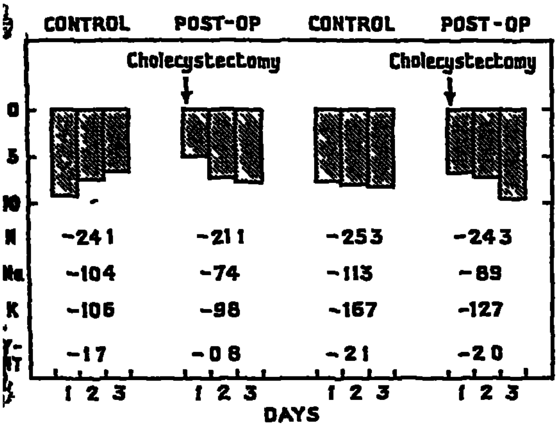
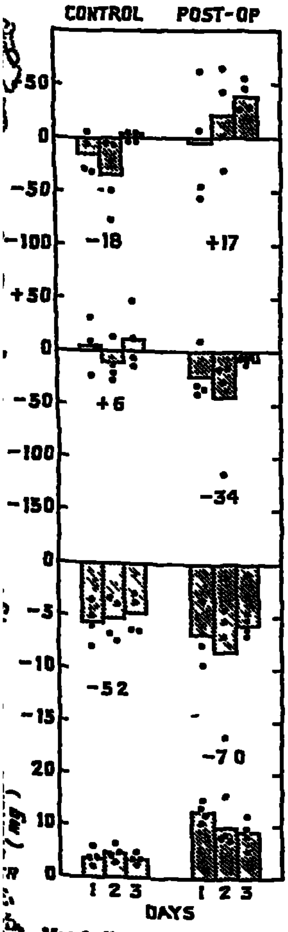
† 5% 'Amigen' (enzymatic protein hydrolysate) in 10% 'Levu (fructose) supplied by Mead Johnson & Co



—Metabolic balances in 2 men, aged 75 and 67, during 3-day trol and 3-day postoperative periods Patients were given amounts of 5% dextrose in water during both periods ogen balance (g), cumulative 3-day nitrogen balance (g), nge in body-weight (kg), and cumulative sodium and potassium ances (mEq), are shown for each period.

nitrogen were not appreciably influenced by sthesia and uncomplicated cholecystectomy



The greatest sodium deficits were observed on the first day of each study period and were followed by a gradual conservation The three women showed postoperative deficits that were slightly greater than those noted in the control period On the other hand, the two men showed slightly greater sodium deficits during the three-day control period than they did postoperatively We think that these slight variations are not significant, and that the deficits of sodium in the control and the postoperative periods can be regarded as comparable

Although there were slight variations in the extent of the cumulative deficits of potassium and nitrogen and loss of body-weight for the control and postoperative periods, the alterations were related primarily to the diet and were not appreciably influenced by the operation The average *daily deficit* of nitrogen was 6 4 g postoperatively for the three women (fig 1) and 7 6 g for the two men (fig 2) in group A These deficits are similar to those exhibited by one healthy woman and two healthy men maintained for three days on a diet similar to that given to the patients in group A The woman had an average *daily nitrogen deficit* of 5 3 g and the men 8 0 and 8 2 g (Holden et al 1957)

—Metabolic balances for sodium, potassium, and nitrogen daily excretion of 17-hydroxycorticoids in 4 female patients ceiving 5% dextrose in water containing about 90 mEq of dium and 80 mEq of potassium during control and post-perative periods

The length of the sodium, potassium, and nitrogen histograms ents the average daily balance for the 4 patients and the *dots* resent the individual daily values for each patient. The numbers w the balance charts represent the average daily balance for each iod.

The remaining eight women (groups B and C) received daily about 90 mEq of sodium and 80 mEq of potassium

The sodium balances of the four women in group B (fig 3) varied only slightly above and below equilibrium, the oldest women (aged 61), who postoperatively showed a three-day cumulative positive balance of 175 mEq of sodium with a three-day intake of 258 mEq of sodium With the exception of this patient, fluctuations of sodium balance during the postoperative period were not unlike those observed in healthy people on a constant diet

There were only slight deviations from equilibrium in potassium balance in both the control and postoperative studies, if one excludes the data obtained from one patient who developed a wound infection during the postoperative period She had pyrexia (100 4–102 2°F) for the first five postoperative days This patient's cumulative postoperative three-day deficits of potassium and nitrogen were 160 mEq and 33 g respectively These deficits are considerably greater than those noted for the other patients in this group and are attributed to the postoperative complication rather than the operative stress If the data obtained from the study of this one patient are excluded, the average daily postoperative deficits of potassium and nitrogen of the remaining three patients in group B were 15 mEq and 5 7 g respectively, which are comparable to that of the female volunteer and the patients *in group A*

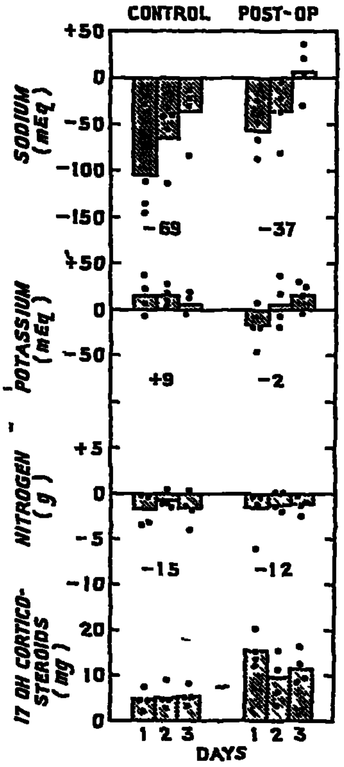


Fig 4—Metabolic balances for sodium, potassium, and nitrogen and daily excretion of 17-hydroxycorticoids in 4 female patients given a solution of 5% protein hydrolysate containing 10% fructose and about 90 mEq of sodium and 80 mEq of potassium

The length of the histogram represents the average daily balance for the 4 patients, and the dots represent the individual daily values for each patient. The numbers below the balance charts represent the average daily balance for each period

The deficits of nitrogen during their control periods (fig 3) are somewhat more difficult to explain Two of the patients showed average daily nitrogen deficits during the control period of only 3 2 g and 4 1 g Such low nitrogen values are not often observed for at least several days after a healthy person is changed from a normal diet to a 500-600-calorie protein-free diet

Thus, measured by sodium, potassium, and nitrogen balances, the postoperative metabolic response of the three patients in group B who had no complications was essentially the same as that of the patients in group

A and the three healthy volunteers in the control period.

The metabolic alterations in the control and postoperative periods of the patients in group C, who received 5% protein hydrolysate in a 10% fructose solution with electrolytes, are shown in fig. 4. The deviations from equilibrium of potassium and nitrogen were less than those shown by the patients in the two other groups. Though their sodium balances varied somewhat, most of the patients showed smaller sodium deficits during the postoperative period than during the control period. The urine volumes were largest in this group who received the protein hydrolysate. The potassium intake was adequate to maintain these four patients, who received a modest amount of protein and calories, close to equilibrium. These four patients lost less body-weight than those who were not given nitrogen and had received only 500–600 calories from the intravenous dextrose (groups A and B). The fact that the patients in group C lost some weight and showed a nitrogen deficit during the control period probably indicates that the caloric intakes of these patients were suboptimal during both the control and the postoperative periods.

All the patients showed a fairly abrupt increase in the urinary excretion of 17-hydroxycorticoids on the day of operation or the first postoperative day. Over the next two to four days these values gradually returned to normal. The cumulative urinary 17-hydroxycorticoid values for the three-day postoperative periods were 50–250% above the values obtained during either the control or the repletion periods. The increase in the urinary excretion of 17-hydroxycorticoids showed no correlation with the postoperative sodium, potassium, or nitrogen balances.

Two patients, who received only dextrose in water, had almost identical postoperative three-day cumulative nitrogen deficits. However, the postoperative increase in the urinary 17-hydroxycorticoids in one of these patients was considerably greater than in the other. One of the other patients, who was given 5% protein hydrolysate in a 10% fructose solution during the control and the postoperative periods, was essentially in nitrogen equilibrium before and after operation. The postoperative increase of urinary 17-hydroxycorticoids of this patient was comparable to that shown by many of the other patients who had greater nitrogen deficits.

It is clear from these studies that the intravenous infusion of a suitable protein hydrolysate, when supported by adequate calories, will either minimise or prevent postoperative wasting of nitrogen and loss of weight, if complications are avoided.

Discussion

The data obtained from this study substantiate our previous findings, that operative trauma and anæsthesia per se are only minor factors in determining the pattern of the metabolic response to surgery. The major factors are the dietary regimens, the complications, the previous nutritional state, and the sex of the patient. We believe that the impression gained by other workers that the postoperative metabolic alterations are obligatory is derived largely from studies in which an insufficient amount of calories, little or no nitrogen, or a nutritionally inadequate protein hydrolysate was given.

In analysing data which we obtained from the study of other patients we have been impressed by the large losses of nitrogen, potassium, and body-weight when extensive blood-loss, necrotic tissue, or serious infection is present. When the intake of calories and protein is adequate, these nitrogen and potassium deficits can often be minimised but may continue until the blood-loss is at least partiall corrected, necrotic tissue removed, or infection controlled.

After operation there is an increase in adrenal activit measured by the urinary output of 17-hydroxycorticoids. These hormones are desirable and are necessary in th resistance to injurious processes and help to maintai homœostasis. The endocrinological response to cholecystectomy in these patients was insufficient to caus changes in the sodium, potassium, and nitrogen balanc from those noted during the control period. Aldosteron and adrenal steroids may often be liberated because of a inadequate intake of various nutrients or because injur has produced physiological changes or variations in bod chemistry. The 17-hydroxycorticoids, like other hormone may help to make available or conserve certain needed substances which influence cellular metbolism or permeability and thus help to tide the injured organism over a period o stress. Increased amounts of antidiuretic hormones an aldosterone are made available when water and sodium are withheld from healthy people. Thus the liberation o such substances after injury or after an elective operatio indicates that the body is conserving water or salt or both. Therefore judicious amounts of these substances shoul be given. We believe that the postoperative metaboli derangements should not necessarily be regarded as bein caused by the increased endocrine activity but, rather, that the output of the various hormones may largely result from the physiological and biochemical change caused by treatment and injury. Our findings lend additional support to the concept of "permissive activity" of the adrenal steroids as postulated by Ingle (1952, 1954 and supported by others (Conn et al. 1954, Engel 1952).

Conclusions

By providing adequate nutrients during the early postoperative period the restoration to a normal state can be aided rather than hindered. Adequate nutrition may also decrease the magnitude of the endocrine response after operation.

✓ There was no correlation in this study between the nitrogen or electrolyte balance and the amount o 17-hydroxycorticoids excreted in the urine.

These studies indicate that, after an uncomplicated operation, the usual patient who does not have extrarenal losses should get daily 75–125 mEq. each of sodium and potassium. Such intakes should maintain a sodium and potassium balance near equilibrium or prevent appreciable deficits and excesses.

✓The loss of weight and wasting of nitrogen and potassium shown by the adult patient who is in an adequate state of nutrition after an uncomplicated elective operation are not obligatory but are primarily the result of the diet he has been given.

The occurrence and severity of postoperative complications are important factors influencing the magnitude of the metabolic response to operation. Though infection, hæmorrhage, tissue damage, &c., may greatly increase the caloric needs and accelerate the metabolic processes, these effects can be minimised by an adequate intake of calories and protein. It is essential, however, that any infection be controlled, necrotic tissue removed, and blood-loss corrected before these alterations due to complications can be eliminated.

SERUM-LIPIDS AND BLOOD-SUGAR LEVELS IN CHILDHOOD DIABETES

O H WOLFF
M.A, M D Cantab, M.R.C.P, D C.H
SENIOR LECTURER

H B SALT
M Sc. Birm., F R I C
BIOCHEMIST

rom the University Department of Pædiatrics and Child Health and the Children's Hospital, Birmingham

THERE is wide agreement that the serum-lipoprotein rises before the development of atheroma (*Circulation* 1956), but it has not yet been proved that the rise causes the disease (Ahrens et al 1957) Less agreement exists about the precise lipoprotein fraction or fractions increased before atheroma

In diabetes mellitus there is a well-recognised tendency for arterial disease to develop prematurely, leading to occlusive coronary disease, retinopathy, or nephropathy It is uncertain to what extent these complications are preventable by strict diabetic control

We have studied the serum-lipids and serum-lipoproteins in diabetic children Though our patients showed no clinical evidence of arterial disease, they must be regarded as almost certain candidates for its development (White 1949), and therefore presented an opportunity for us to define the lipoprotein abnormality in the pre-atheromatous diabetic patient We have also considered that abnormality in relation to such other factors as blood-sugar level, age, and duration of diabetes

Patients and Methods

A study was first made of the levels of lipids and of lipoproteins in the serum of 35 children attending the diabetes clinic

Our diabetic regime includes a diet wherein only the carbohydrate is regulated, but an ample supply of carbohydrate is allowed—e g, 200–250 g for a child aged 8/10 years All the children receive a single injection of insulin-zinc suspension twenty to thirty minutes before breakfast Blood for analysis was taken at a routine monthly visit to the clinic, neither parent nor child knowing beforehand that any special test would be applied The clinic takes place in the afternoon, hence the blood was obtained two or three hours after the main meal, which contained 50–70 g of carbohydrate This explains why in many patients the blood-sugar level was high, even though the patients were all in good health and clinically free from diabetic complications, and routine examinations of urine in the patients' homes every morning and night usually indicated good or fair diabetic control

Serum-lipoprotein was separated [illegible]trophoretically on absorbent paper into omega, beta, and alpha [illegible]ions, after staining with oil red O, the total lipid and the fractio[illegible]ere estimated by the method described by Salt and Wolff (1957) The usual normal values are included in table II

Analyses of sera for total cholesterol (Sackett 1925), total esterified fatty acid (Stern and Shapiro 1953), and lipid phosphorus (method adapted from Gomori 1942) were also made.

Blood-sugar values were estimated by the Folin-Wu micro-technique, using unlaked blood in Herbert and Bourne's method (Harrison 1937)

In calculations a representative molecular weight of 277 2 was used for fatty acid, phospholipid (M.W 806) was obtained by lipid phosphorus × 26

We regard as conventional normal ranges for children cholesterol 20–250, esterified fatty acid 190–450, and phospholipid 160–310 mg per 100 ml of serum

Results

Scrutiny of the individual results from the 35 diabetes-clinic (treated) patients showed that only a few values for total lipid, beta-lipoprotein, esterified fatty acid, and cholesterol were above the normal range Slightly raised levels of phospholipid were common, but here, as with other serum-lipid components, doubt exists about the precise extent of the normal ranges

The analytical data were then collected into two subgroups according to the patients' blood-sugar level—A, below, and B, above, 200 mg per 100 ml A summary of the results is given in table I, together with the values for t and P (Fisher 1941), which furnish a statistical value of the magnitude and significance of the differences between the means

The two subgroups are not distinctive in age-distribution, insulin dosage, or duration of diabetes There is a trend in subgroup B toward a larger amount of total lipid in the serum Of the three lipoprotein-lipid fractions the beta-fraction exclusively is significantly larger in subgroup B The levels of cholesterol and of total esterified fatty acid in the serum are also significantly higher in subgroup B, but phospholipid shows no significant difference between the two groups

To study more closely the correlation between the lipoprotein-lipid fractions and the blood-sugar level, the results were divided into five groups according to the patients' blood-sugar levels (up to 100 mg per 100 ml, 100–200 mg and so on), and for each group mean values for the lipoprotein fractions were calculated The results of this analysis (fig 1) show a progressive rise in the beta-lipoprotein lipid with each incremental step in the blood-sugar level in the higher ranges of blood-sugar In contrast the alpha and omega fractions show no variation in relation to blood-sugar

No relationship was apparent between any other factors, such as age of patient, degree of diabetic control assessed by long-term review, and the several serum-lipoprotein fractions

Serial Observations in Individual Patients

Our first studies were based on the examination of a group of diabetic children all in good or fair control In further studies we have attempted to determine whether the correlation between certain serum-lipids and blood-sugar levels exists also in the individual diabetic patient.

Besides the method already described, the level of total lipid in the serum was also estimated by the method of de la Huerga et al (1953) Usually the results by the two methods were in fairly close agreement, on the few

occasions (mainly high levels) when there was substantial disagreement the estimations of total lipid by de la Huerga's method were preferred These were regarded as the more correct on evidence from computations made by summation of the levels of esterified fatty acid, cholesterol, and glycerophosphoryl-choline (phospholipid residue) in the serum

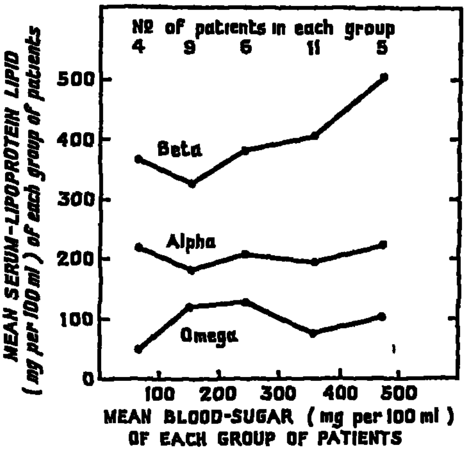

Fig 1—Relationship between mean blood-sugar level and mean level of lipoprotein-lipid fractions in serum of diabetics under control Each mean value is derived from a number of patients grouped by blood-sugar ranges up to 100, 100 to 200, &c , mg per 100 ml

Three previously untreated diabetic children were examined before and at various intervals after the start of insulin treatment In addition, one diabetic girl, previously under treatment, was studied both in diabetic coma and during her recovery, which was delayed by the development of peripheral neuritis and gangrene

In the following case-reports only the salient features are mentioned The laboratory findings in the four cases are presented in table II

Case-reports

Case 1—A girl, aged 6 years, developed symptoms of diabetes mellitus in *March*, 1957 On admission to the Children's Hospital in May, 1957, her general condition was fair, and she was fully conscious and only slightly dehydrated Her urine contained sugar (2 g per 100 ml) and ketones The carbon-dioxide combining power of the serum was 43 volumes % (19 mEq per litre) The levels of blood-sugar, serum-total lipid, and serum-beta-lipoprotein before and for forty hours after the institution of insulin treatment are shown in fig 2

A greatly increased amount of beta-lipid was mainly responsible for the initially enormous increase in the total lipid, within twenty-four hours of the start of treatment the beta fraction had fallen to within normal limits It is particularly important to note that the precipitous fall of the blood-sugar level to 31 mg per 100 ml which followed the first injection of insulin (20 units) was accompanied by an equally rapid fall of the level of the beta-lipoprotein fraction

Case 2—A girl, aged 11 years, developed symptoms of diabetes mellitus in February, 1957, and was admitted to hospital in June, when she was found to be very thin, with a dry skin, she was fully conscious Her urine contained glucose (2 g per 100 ml) but only a trace of ketones, acidosis was only moderate, with a carbon-dioxide combining power of 37 volumes % (16 5 mEq per litre) Again the beta-lipoprotein level quickly returned to normal, though not quite so rapidly as in case 1

Case 3—A girl, aged 3 years, developed symptoms of diabetes mellitus in October, 1957, three weeks later, on *admission to hospital, she was fully conscious* and moderately dehydrated, and her urine contained glucose (2 g per 100 ml) and ketones In this child, although ketosis was abolished during the first day of insulin treatment, the fall in blood-sugar level was only slight, and correspondingly the fall in serum-beta-lipoprotein level was slight

Case 4—A girl, aged 12 years, who had developed diabetes mellitus at the age of 3 years, was readmitted in December, 1956, in diabetic coma, with a serum carbon-dioxide combining power of 15 volumes % (7 mEq per litre) After a stormy course her condition improved, but then she developed peripheral neuritis and gangrene of a toe A second specimen of blood was examined four and a half months later, when those complications were still present It is important to note that the lipoprotein

abnormality was present before the vascular complications, and that later, when the blood-sugar level was 200 mg. per 100 ml., the lipoprotein pattern was normal despite the persistence of the vascular complications.

Table II shows that in these patients the beta-lipoprotein levels closely followed the blood-sugar levels, but that no corresponding changes took place in the levels of the omega and alpha fractions of lipoproteins. In all uncontrolled patients the beta-lipoprotein peak occupied an advanced electrophoretic position, and in some instances that peak appeared to be heterogeneous with a subfraction (designated *) lying ahead of the main peak. Moreover case 4, when in diabetic coma, showed a fraction of alpha-lipoprotein in a position ahead of albumin—a feature already reported by Salt and Wolff (1957).

Discussion

Classical investigations into the disorder of lipid metabolism in diabetes mellitus (summarised by Peters and Van Slyke 1946) led to the view that, in severe cases with a tendency to ketosis and acidosis, there was a general increase of all the blood-lipids. The degree of lipæmia was thought to depend not on the severity of the diabetes but rather on the success of insulin therapy in controlling the disorder of carbohydrate metabolism. In diabetic patients who utilise sufficient carbohydrate the serum-lipid levels and patterns were regarded as substantially normal.

Our findings in children, which now include observations of the serum-lipoprotein fractions, are in the main in agreement with the classical view. The three initially untreated patients, in none of whom ketosis was severe, and the one who developed diabetic coma all presented with high levels of total lipids and beta fractions in the serum. Under insulin treatment, as the blood-sugar level fell, those high serum-lipid levels reverted either to normal or, in case 3 observed for a short time only, toward normal.

Among the diabetes-clinic patients the mean values in both subgroups all lay within normal limits, except the mean phospholipid levels. Attention thus became focused on certain statistically significant differences between the means in the two subgroups. In subgroup B the levels of cholesterol, esterified fatty acid, and beta-lipoprotein lipid in the serum were significantly higher than those in subgroup A. It seemed reasonable to infer that the increased lipid of the beta-lipoprotein complex was mainly cholesteryl ester, with some phospholipid, perhaps, in certain cases. However, we emphasise that the principal finding in this study is the higher level of beta-lipoprotein in the serum of diabetic children with higher blood-sugar levels, irrespective of the exact nature of the lipid constituents of the beta-lipoprotein complex.

Bowen (1951) examined by Tiselius electrophoresis the beta-globulin-bound lipid in the sera of healthy people and diabetic patients; he correlated the total cholesterol in the serum with extractable beta-lipid and found no significant difference between the correlation established for the healthy people and that for the well-controlled diabetic patients.

Baker et al. (1955), who studied the serum-lipoproteins by paper electrophoresis in diabetes-clinic patients, mainly adults, and in controls, found the beta/alpha ratio significantly higher in the diabetic patients, especially when the diabetes was accompanied by clinical evidence of atheroma. Such high beta/alpha ratios have been described in non-diabetic atherosclerotic patients by Rosenberg et al. (1954).

Keiding et al. (1952), Barach and Lowy (1952), and Tuller et al. (1954) investigated the levels of cholesterol and of ultracentrifugally separated lipoproteins in the serum of diabetic patients with vascular complications. Although the relationships are not fully understood, there appear to be definite links between disorders of serum-lipids and the development of arterial disease in diabetes. In the present case 4 the lipid abnormality preceded the vascular complications, but was reversible despite persistence of those complications.

Harris et al. (1953) showed that the hyperlipæmia of diabetic acidosis involves all fractions of the serum-lipids, especially the triglyceride fat.

Waagstein (1955) correlated the amounts of total lipids in the serum with blood-sugar levels in diabetic patients.

Hirsch et al. (1953) correlated the increased amounts of esterified fatty acids in the serum with high blood-sugar levels in diabetics.

Our results suggest that, during the course of diabetic illness, there may be repeated intermittent rises of level of beta-lipoprotein lipid in the serum whenever the blood-sugar level is raised through inadequacy of insulin action. The main ground for this speculation lies in the finding of statistically higher levels of beta-lipoprotein lipid in the serum of patients who, though free from ketosis and acidosis, had higher blood-sugar levels at the time of examination.

Further support is seen in the speed with which the levels of the beta-lipoprotein fraction returned to normal in the previously untreated patients as the blood-sugar levels fell under treatment with insulin, even when initial ketosis had not been severe. How rapidly the level of beta-lipoprotein in the serum follows the blood-sugar level in the controlled diabetic cannot be deduced from the studies reported here

In considering the several factors which may determine the rise of the serum-beta-lipoprotein level, hæmoconcentration (Harris et al 1953) may be set aside as regards our group of clinic patients Similarly, normal alimentary absorption, which is known to lead to an intermittent increase in the omega (chylomicron) fraction in the serum, without significantly affecting the beta and alpha fractions, can be disregarded, provided that utilisation is unimpaired

The important mechanisms of mobilisation of lipid from the adipose-tissue stores must next be considered It is known that, when carbohydrate is unavailable, lipid is mobilised to meet energy requirements, in diabetes a raised blood-sugar presumably indicates unavailability of glucose The mobilised lipid may be non-esterified fatty acid bound to albumin (Dole 1956, Gordon and Cherkes 1956, R S Gordon 1957) or very-low-density lipoproteins including chylomicrons (Havel 1957)

Although in part the mobilised material may consist initially of triglyceride fat, Salt and Wolff (1957) have observed that, in malnutritional states, the beta-lipoprotein level in the serum was raised and, in addition, the beta-lipoprotein took up an advanced electrophoretic position—a feature again noted in all our diabetic patients who were either untreated or out of control

It seems that lipolysis of mobilised lipid liberates fatty acid, and this may attach itself to beta-lipoprotein (besides albumin) and in extreme cases even to alpha-lipoprotein, thus causing increased electrophoretic mobilities of those lipoprotein fractions

Lastly, in considering raised levels of the serum lipoproteins, it is uncertain whether, or to what extent, there may be impairment of utilisation If this is a factor, both the quantity and the lability of absorbed alimentary lipid deserve consideration

The outstanding problem of childhood diabetes is the prevention of arterial complications Possibly this could be achieved through control of the blood-lipid levels, especially that of the beta-lipoprotein fraction To this end our findings confirm the desirability of maintaining a strict control of blood-sugar levels because this in turn would limit the degree of intermittent or persistent hyperlipæmia However, the difficulties of maintaining strict control, particularly in children, are considerable, and some additional and more direct attack on the hyperlipæmia therefore seems desirable

The feeding of fats containing a high proportion of unsaturated fatty acids has been widely advocated recently as a means of lowering blood-lipid levels in the hope of preventing atherosclerosis Already Kinsell et al (1954) and E S Gordon (1957) have fed such diets to diabetic patients and were successful in lowering the levels of certain lipid constituents in the blood A similar prolonged dietary trial in diabetic children before the onset of arterial disease should yield important evidence about whether or not a blood-lipid abnormality is a cause of the arterial complications in diabetes By inference it might even throw further light on the ætiology of atheroma in non-diabetic persons So far we have fed to one diabetic patient an emulsion of unsaturated triglyceride with resultant lowering of her serum-lipid level Further experiments along these lines are planned

Summary

Specimens of blood from 35 children, all under good or fair diabetic control, were analysed for the levels of sugar in the blood and for the levels of total lipid, lipoprotein-lipid in three electrophoretic fractions, cholesterol, esterified fatty acid, and phospholipid in the serum

The mean levels of beta-lipoprotein lipid, cholesterol, and esterified fatty acid in the serum were significantly higher in the children with blood-sugar levels above 200 mg per 100 ml than in those with levels below 200 mg per 100 ml A progressive rise of beta-lipoprotein level in the serum was observed with a rising blood-sugar level

In three hitherto untreated patients with only moderate or slight ketosis the initial levels of serum-lipid were high, the rise being largely due to the beta-lipoprotein fraction Under treatment with insulin, as the blood-sugar level fell the level of beta-lipoprotein in the serum also fell, in 2 cases it reverted to normal within one or a few days

One girl, a long-known diabetic, was found to have a very high level of total lipid and beta-fraction in her serum when admitted in coma Her recovery was complicated by gangrene and peripheral neuritis Four months after the coma, when the complications were still present, her serum-lipoprotein pattern was within the normal limits when the blood-sugar level was near normal In this case the serum-lipid abnormality preceded the development of arterial disease but remained reversible despite the persistence of complications

The results support a hypothesis that hyper-beta-lipoproteinæmia develops whenever insufficient carbohydrate is available for metabolic needs The high levels of beta-lipoprotein and cholesterol in the serum resemble those known to precede the development of atheroma in non-diabetic persons Although the increased amount of beta-lipoprotein has not been proved to cause the early development of arterial complications in juvenile diabetics, the facts strongly suggest the desirability of maintaining normal serum-lipid patterns

We thank Prof J M Smellie for his interest and encouragement, Mr B Rudd for his technical assistance, and Dr M Weeks for her help in the diabetes clinic

INFLUENCE OF POSITION AND ACTIVITY ON THE SECRETION OF ALDOSTERONE*

ALEX F MULLER
M.D

ELIZABETH L MANNING
A B

ANNE M RIONDEL
Ing Chem

From the Department of Medicine in the University of Geneva and the Central Laboratory, Hôpital Cantonal, Switzerland

WHEREAS the diurnal rhythm in the urinary excretion of corticosteroids is well established, comparatively little is known about the day-and-night cycle of aldosterone Most workers have detected a diurnal pattern in ambulant normal persons On the other hand, Garrod, Simpson, and Tait (1957) did not find one in normal subjects who were recumbent, and this strongly suggested that the day-and-night difference in excretion of aldosterone depends solely on the position and activity of the person concerned To ascertain whether this is so, we made a series of observations on subjects who kept changing their position and activity

Methods

The subjects studied were healthy persons and a hypophyseal dwarf aged 19 All were maintained on a constant diet containing relatively little sodium On two occasions the patient with pituitary insufficiency was given prednisone by mouth every six hours

Urine was collected every twelve hours starting from 7 A.M and analysed for sodium and potassium in a flame photometer Creatinine was determined by the method of Folin (Peters 1942) and chloride by that of Sanz and Brechbuhler (1955) The urinary 17-hydroxycorticosteroids were determined by a modification of Reddy's method Hertoghe et al 1955) in the normal subjects and by the method of Norymberski and Stubbs (1954) in the hypophyseal dwarf Aldosterone was analysed chromatographically after acidification of the urine at pH 1 for twenty-four hours (method *d* of Neher and Wettstein 1955)

Results

Fig 1 shows the findings in a woman of 32 She ate three meals a day (at the same hours every day) containing less than 12 mEq of sodium In the first experiment NaCl 1 g (17 mEq) was added to each meal, whereas in the second experiment she ate the 51 mEq of salt during the night She maintained her normal activity, working regular hours, and always went to bed between 10 and 11 o'clock at night Despite this variation in the salt intake, there was in both experiments a clearcut regular day-and-night difference in the urinary aldosterone excretion The urinary output of sodium, however, was not greater by day than at night No correlation between the urinary excretion of aldosterone and that of sodium was found Potassium, 17-hydroxycorticosteroids, and water were always excreted in greater quantities by day than at night

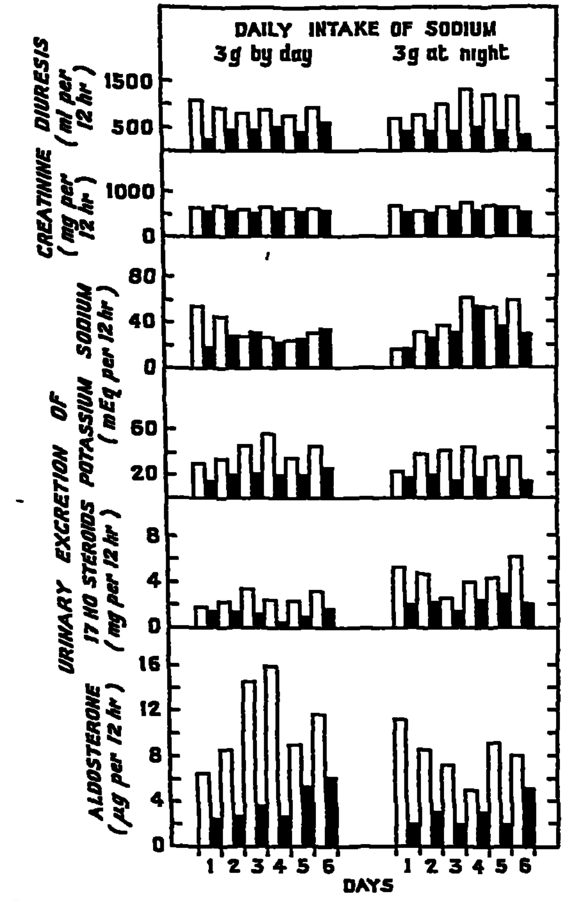

Fig 1—Influence of sodium intake on daily pattern of urinary excretion of aldosterone in a healthy woman leading a normal life Whether salt is taken by day or at night, urinary excretion of aldosterone, 17-hydroxycorticosteroids, and potassium is greater by day than at night. Urinary excretion of sodium has no definite day-and-night rhythm and no correlation with excretion of aldosterone

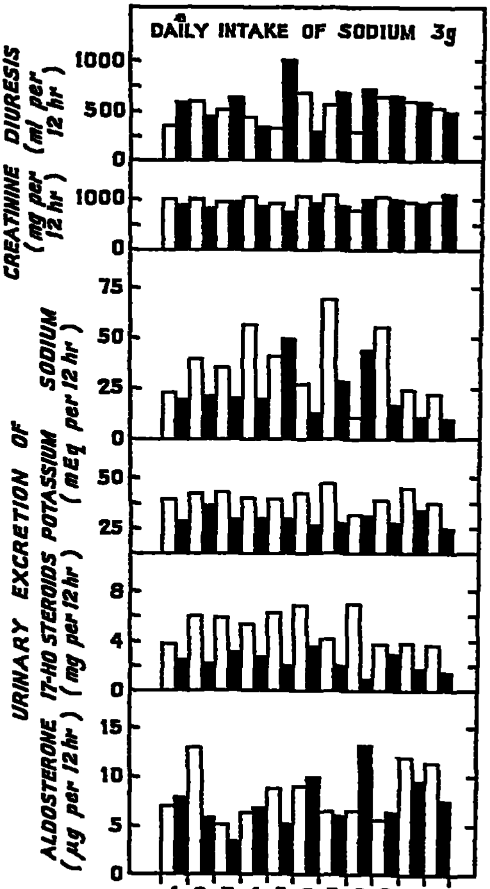

Fig 2—Diurnal and nocturnal urinary excretion of aldosterone in a healthy man with very irregular working hours, night and day Note absence of regular day-and-night pattern of excretion of aldosterone Contrast fig 1

---

* This work was made possible by a grant of the Fondation Nationale Suisse de la Recherche Scientifique It was presented in part before the Swiss Society of Internal Medicine, Schaffhausen, May 11, 1957

Fig 2 illustrates a similar study A man, aged 35, took a constant diet containing 3 g (50 mEq) of sodium daily, but he ate his meals at different hours of the day and night He was working irregular hours during the whole experiment, and his sleep was often interrupted On several occasions he was up and working a good part of the night In these circumstances there was no day-and-night difference in the excretion of aldosterone The output of urine and the excretion of creatinine were also less regular than in the previous study However, this time more sodium was excreted by day than at night The daily pattern of excretion of potassium and 17-hydroxycorticosteroids was identical with that found in the previous study

Fig 3 shows the results of a metabolic study of a healthy woman, aged 33, who intentionally changed position and activity during the day, whereas at night she was always horizontal in bed and inactive On the first, fifth, sixth, seventh, and ninth days she was up and ambulant, carrying on her usual activities On the second, third, fourth, and eighth days she lay flat and inactive in bed day and night The increased excretion of aldosterone during the day was clearly seen whenever she was up and working during the daytime As soon as she lay flat for twenty-four hours, the rhythm was interrupted and sometimes even reversed, with a larger excretion at night The overall excretion of aldosterone was greater when she was ambulant than when she was lying flat and inactive in bed Similar changes related to position and activity were found in the excretion of sodium While the woman was ambulant she actively retained sodium (89 and 8 mEq) and there was no difference in excretion between day and night As soon as she lay flat throughout the twenty-four hours, not only was sodium excreted (49 and 40 mEq) but also a daily pattern became manifest, with increased excretion during the day During this same period, for the first time, the ratio of aldosterone to sodium in the urine was inverted The excretion of chloride and the output of water had practically the same pattern as that of sodium, whereas potassium was excreted mainly by day In contrast to the aldosterone excretion pattern, the urinary 17-hydroxycorticosteroids were, throughout the study consistently higher during the day than at night, despite changes in position and activity

Fig 4 shows the findings in the male hypophyseal dwarf He was ambulant from 7 A M to 10 P M The rest of the time he slept flat in bed His urine was collected separately for those periods, and, since the periods were unequal, the results had to be expressed per hour During the last five days of the experiment the patient was given prednisone Despite his upright position and his activity there was no difference in urinary excretion of aldosterone between the day and the night when glucocorticoids (in his case prednisone) were withheld, but the increase in excretion of sodium by day was striking and apparently independent of the aldosterone excretion The night diuresis was also conspicuous and disappeared under treatment with prednisone The excretion of

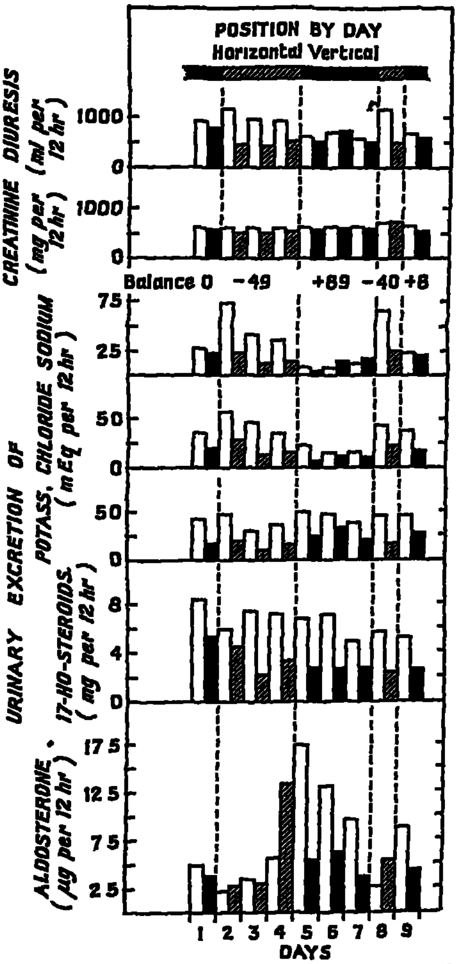

Fig 3—Influence of position on daily rhythm of urinary excretion of aldosterone in a woman, aged 33, who was always flat in bed and inactive at night but varied her position and activity by day Note discrepancy between day-and-night patterns of urinary excretion of aldosterone and 17-hydroxycorticosteroids, excellent correlation between those of aldosterone and sodium when the woman lay flat, and difference in sodium balance according to position

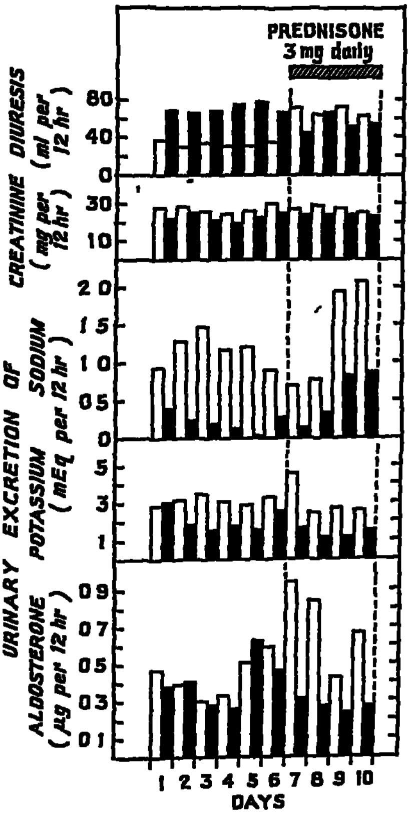

Fig 4

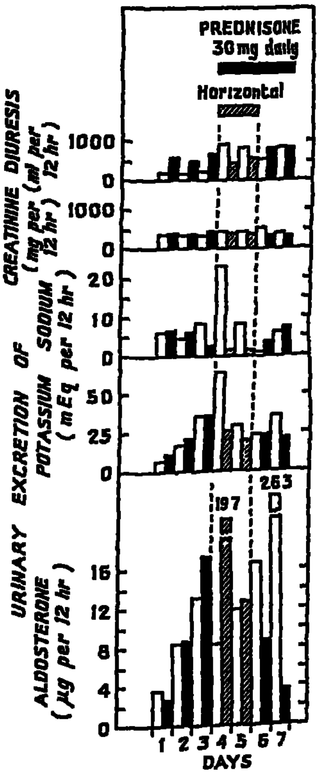

Fig 5

Fig 4—Daily urinary excretion of aldosterone in a youth, aged 19, with pituitary insufficiency Note absence of regular day-and-night pattern of aldosterone except under treatment with prednisone Sodium excretion, on the other hand, is consistently higher during the day Diuresis at night.

Fig 5—Same patient Influence of prednisone on urinary excretion of aldosterone in relation to position Note increased excretion of aldosterone by day when he was up and active, and important changes in diuresis and excretion of sodium, potassium, and aldosterone under treatment with prednisone and on changing position

potassium by day was again increased and hardly influenced by the administration of prednisone Despite the pituitary insufficiency, the excretion of 17-hydroxycorticosteroids still kept its daily pattern, with slightly increased excretion during the day (Not shown on the figure)

In a second experiment the same hypophyseal dwarf was again given prednisone, but this time while lying flat in bed for forty-eight hours (fig 5) The two experiments show that, when this patient was having prednisone, his urinary excretion of aldosterone increased in the daytime if he was ambulant and active but not if he was recumbent That is to say, the glucocorticoids (prednisone) per se did not alter the secretion of aldosterone their action seemed to be permissive Once again the excretion of sodium was not related to that of aldosterone, except to some extent when the patient was recumbent The output of urine was affected by the prednisone, and the excretion of potassium was very irregular

Discussion

These data, as well as those published elsewhere (Muller et al 1957), demonstrate unequivocally that position and activity influence the urinary excretion of aldosterone, whereas taking small amounts of salt at night instead of by day has no such influence On the basis of our earlier findings and those of other workers the increased urinary excretion of aldosterone can be taken, in the circumstances of the experiments, as reflecting increased secretion of aldosterone by the adrenal glands

Bartter (1957) has shown that a decrease in blood-volume stimulates the secretion of aldosterone Since (as has long been known) standing contracts the "effective blood-volume", it is very likely that the increase in urinary excretion of aldosterone really reflects a homœostatic mechanism set off by a decreased effective blood-volume due to the effect of position and exercise on the circulating blood-volume As Peters (1948) suggested, this mechanism may operate also in hæmorrhage and in congestive heart-failure

The retention and elimination of sodium shown at different periods in fig 3 certainly coincide, respectively, with increased and with decreased secretion of aldosterone It therefore seems that the increased retention of sodium on standing and exercise is caused by (among other factors) an increased secretion of aldosterone, which in turn is caused by contraction of the effective blood-volume In a similar way rest in bed increases the excretion of sodium by reducing the secretion of aldosterone

On the other hand, our results show, in the ambulant person, no correlation between the day-and-night cycles of sodium and of aldosterone They are therefore consistent with the view that alterations in the effective blood-volume on standing and exercise not only influence the secretion of aldosterone but also initiate acute renal adjustments in sodium excretion (Epstein et al 1951) These renal mechanisms seem to be independent of aldosterone, which explains their presence in Addison's disease The fact that the patient with pituitary insufficiency showed a constant difference between his diurnal and his nocturnal excretion of sodium, whether or not there was any such a difference in his excretion of aldosterone (fig 4), is another example of this dissociation between the sodium and aldosterone cycles In the recumbent subjects, however, the ratio between sodium and aldosterone in the urine tended to be inverted

The absence of a day-and-night difference in the excretion of aldosterone by the ambulant active patient with pituitary insufficiency is difficult to explain, so is the effect of prednisone in re-establishing this difference The fact that under treatment with prednisone this rhythm appears only if the patient is ambulant is another example illustrating the permissive rôle of the glucocorticoids Standing erect, by increasing the capillary filtration and the pooling of blood in the limbs, decreases both the effective and the total blood-volumes Possibly cortisone and prednisone influence this pooling of blood by increasing capillary permeability, whereby the effective blood-volume decreases, and the secretion of aldosterone is consequently stimulated

Summary

The difference between diurnal and nocturnal excretion of aldosterone in the urine was studied in three healthy people and one patient with pituitary insufficiency

The findings unequivocally demonstrate the influence of position and activity on the daily pattern of aldosterone excretion A small change in the diurnal and nocturnal intake of sodium chloride has no influence on this pattern The greater excretion of aldosterone by day seems to be the result of the erect position and activity A contraction of the effective blood-volume, as a result of standing and exercise, is postulated as the physiological stimulus of the aldosterone secretion However, the changes in sodium excretion due to position and exercise are mediated not only by the secretion of aldosterone but also by adjustments in renal mechanisms

In the patient with pituitary insufficiency the excretion of aldosterone was not greater by day than at night, despite ambulation and activity Treatment with prednisone re-established the greater excretion of aldosterone by day than at night, provided the patient was up and active, but not when he was lying flat

ROYAL DEVON AND EXETER HOSPITAL

Despite all treatment, the case-mortality of generalised tetanus is still high The physician has often been faced with the dilemma of a patient who may die either of cerebral anoxia due to tetanic spasms, or of respiratory paralysis (with aspiration of secretions) caused by increasing the dosage of sedative and relaxant drugs

Drawing on their extensive experience of bulbar poliomyelitis, Lassen, Ibsen, and their coworkers (1953, 1954,

1956) realised that the problem of respiratory paralysis can be solved by introducing, through a tracheostomy, a cuffed tube, through which artificial respiration may be applied They treated their tetanus patients by long-continued anæsthesia (N_2O and O_2), sometimes combined with administration of tubocurarine chloride A case treated successfully on these lines was reported by Shackleton (1954), who administered N_2O and O_2 with suxamethonium The use of full curarisation and intermittent positive-pressure respiration (I P P R) in tetanus has been reported by Honey et al (1954), Mollaret et al (1955), and Crampton Smith et al (1956)

We have treated two patients successfully by methods evolved by the Oxford workers, and we acknowledge with gratitude the assistance which we have received from Dr Ritchie Russell, Dr J M K Spalding, and, in particular, Dr Crampton Smith, whom we consulted frequently

Case-reports

THE FIRST CASE

A girl, aged 6, fell and sustained a tiny puncture wound on her knee on April 20, 1957 Seven days later tetanus came on rapidly, and four hours later she was admitted to hospital with severe spasms

Initial treatment After a preliminary test dose, antitetanic serum 100,000 units was given in the first twenty-four hours Further doses of 50,000 units each were given on the fourth, eighth, and twelfth days preceded by promethazine hydrochloride by mouth 25 mg there was no adverse reaction Penicillin was given for the first ten days, then withheld, and then given again from the twelfth day for twenty-one days following serious deterioration in the patient's general condition

Because paraldehyde and barbiturates did not control her spasms, mephenesin was added on the second day, 250 mg being given every half-hour by stomach-tube In spite of this the spasms became more frequent and more severe Her temperature rose steadily despite tepid sponging, ice packs, and the use of a fan, and reached 107°F forty-eight hours after the start of treatment

Artificial respiration In view of this deterioration, and in particular because of our inability to control her temperature, it was decided to give tubocurarine and maintain artificial respiration with a Radcliffe intermittent positive-pressure respirator

The child was anæsthetised by one of us (K J P) with nitrous oxide and oxygen, complete relaxation being obtained with tubocurarine After a cuffed endotracheal tube had been introduced, manual respiration was applied with a bag Tracheotomy was then performed by Mr Philip Scott, after which a short cuffed endotracheal tube was introduced and connected to a Radcliffe respirator Administration of nitrous oxide was discontinued, but oxygen 1 litre per minute was given with the inspired air The respirator was adjusted to give a minute volume of 4–5 litres

The following routine was then adopted

(1) Tubocurarine 10–15 mg was given intramuscularly with hyaluronidase, except when intravenous fluids were being given, when the tubocurarine was added with them The need of a further dose of tubocurarine was indicated by the appearance of muscular twitchings, which were regarded as modified tetanic spasms, and by any decrease in the respiratory minute volume which could not be accounted for by obstruction of the airway The daily requirement of tubocurarine varied between 95 and 250 mg (average 160 mg)

(2) Percussion and postural drainage were applied four-hourly during the day by the physiotherapist, who often gave additional treatment during the night

(3) The trachea and bronchi were cleared of secretions by suction through a soft rubber catheter each time the patient was turned, or more frequently if required Bronchoscopy was required on only two occasions Pharyngeal secretions were sucked out, and the cuff of the endotracheal tube deflated for two or three minutes every two hours

(4) The respiratory minute volume was measured half-hourly and any decrease remedied by suction, with further tubocurarine, or by adjustment of the respirator

(5) Temperature and pulse were recorded half-hourly, and a rise was found to be a useful indication of segmental or lobar pulmonary collapse

(6) The stomach-tube was aspirated hourly, and feeds of a fortified milk mixture* were given to supply the patient's estimated requirements of 1600 calories and 1500 ml of fluid daily Vitamins were also given routinely through the tube A transient increase in the gastric aspirations twenty-four hours after curarisation made it necessary to give intravenous feeding for twelve hours, after which normal gastric function returned and tube feeding was therefore resumed

Progress

On the fourth day Mr C C Jeffery excised the wound on the knee, removing a small piece of woody stem from a golden-rod plant, surrounded by a pocket of pus, from which *Clostridium tetani* was later isolated The wound was cleaned with hydrogen peroxide and sutured

On the eleventh day a severe episode of lobar collapse with cyanosis was followed by a rapid rise in temperature and pulse-rate, even after re-expansion of the lung had been obtained by bronchoscopy Four hours later, severe peripheral circulatory failure developed with unrecordable blood-pressure An intravenous infusion of noradrenaline was started immediately The amount of noradrenaline required to raise the blood-pressure to normal levels was so great that 16 mg had to be added to each 500 ml of 5% dextrose By this means the systolic blood-pressure was restored to 110 mm Hg after five hours After remaining critically ill for twenty-four hours the patient gradually needed less noradrenaline until, after forty hours, it was withdrawn completely

Chloramphenicol treatment of a superficial infection of the tracheostomy was begun on the day on which she developed peripheral circulatory failure, and eighteen hours later penicillin therapy was restarted and antitetanic serum 50,000 units was given The patient's temperature and pulse-rate then fell rapidly, reaching their previous levels after twenty-four hours

Her requirements of tubocurarine remained fairly constant for fifteen days, until, on the evening of May 15, the signs indicating the need for a further injection did not appear, and no tubocurarine was given Twelve hours after her last dose of tubocurarine the patient was taken off the respirator, having had I P P R for sixteen days Radiography showed that her chest was clear and her spine had no collapsed vertebra

THE SECOND CASE

A girl, aged 10, fell off a seesaw on June 23, 1957, sustaining a compound fracture of her right radius and ulna She was admitted to a local hospital, where the wound was cleaned and excised and the fracture reduced and put into plaster She was not given antitetanic serum Five days after her injury she developed tetanus, and was transferred to the Royal Devon and Exeter Hospital, accompanied in the ambulance by a consultant anæsthetist equipped with apparatus for intubation if required

Initial Treatment

After a preliminary test dose, antitetanic serum 200,000 units was given on the first day, and further injections of 100,000 units each were given on the second, third, fourth, and sixth days

The compound-fracture wound was opened up widely by Mr Jeffery, and *Cl tetani* was subsequently cultured from it Penicillin was given throughout the first three weeks in hospital

---

* Fortified Milk Mixture 2 pints milk (1136 ml), 2 oz glucose (56 g), 2 oz 'Casilan (56 g), 2 eggs, 1 teaspoon 'Marmite , ½ teaspoon salt. Calorie value 1364

Mephenesin 200 mg half-hourly and quinalbarbitone gr $1^1/_2$ six-hourly were given by stomach-tube and paraldehyde 4 drachms by the same route as required to control the spasms (usually every three or four hours). Although for three days the spasms were fairly well controlled, the amount of paraldehyde required rendered the child deeply unconscious Although physiotherapy and postural drainage were applied four-hourly, on the fourth day of her illness her cough reflex became so diminished that she had a severe episode of bronchial obstruction with profound cyanosis A large amount of inspissated mucus was found in her mouth and pharynx Bronchoscopy was done immediately (K J P), and a plug of mucus was removed from the right main bronchus

Artificial Respiration

In view of these dangerous respiratory complications, treatment with tubocurarine and I P P R was instituted without delay Mr Raymond Hinde kindly carried out the tracheotomy

The general management was then similar to that in case 1 The amount of tubocurarine needed was 380–500 mg (average 440 mg) daily, and feeds of the fortified milk mixture were given to provide 2000 calories and 2 litres of fluid daily The respiratory minute volume was maintained at 6 litres per minute Seven hours after treatment with tubocurarine had been started, tube feeding had to be discontinued because large quantities of fluids were being aspirated from the stomach After thirty hours, during which time fluids were given intravenously, tube feeding was successfully resumed Transient collapse of her right upper lobe occurred on the third day of I P P R, but in general the chest remained remarkably clear

The child's need of tubocurarine remained fairly constant until the thirteenth day, when the drug was withheld without the development of tetanic spasms On July 15, after fourteen days' I P P R, she was finally taken off the respirator Radiography showed some vertebral compression of the 4th, 5th, and 6th dorsal vertebræ In all other respects her recovery was complete

DISCUSSION

Curarisation and I P.P R

For these two patients treatment with tubocurarine and I P P R was started only after large doses of hypnotic drugs and mephenesin had failed to control the spasms Indeed it must be admitted that our second patient was allowed to reach a point at which the laryngeal reflexes were dangerously depressed by sedation In the light of our experience with these two patients it now seems to us that all cases of tetanus in which the spasms cannot be controlled by moderate sedation and mephenesin should be treated by complete paralysis and I P P R

A further indication for the administration of tubocurarine in our first patient was our inability to control her extreme pyrexia Vigorous surface-cooling produced only chilling of the skin and violent shivering It was not until this shivering had been overcome by complete paralysis that the temperature could be lowered It did not seem advisable or necessary to enhance this treatment with a lytic cocktail as advocated by Rossi et al (1954)

After initial intravenous injection of tubocurarine, satisfactory results were obtained with intramuscular injection of the drug, usually with hyaluronidase Relaxation was evident in five minutes

Sedatives and hypnotic drugs were used sparingly in the later stages of treatment in case 1 and scarcely at all in case 2 Ten days after the cessation of treatment neither of these children, both of whom are of at least average intelligence, could recall any detail of their period of artificial respiration In particular they have no recollection of any pain Possibly the respirator may have induced a slight degree of hyperventilation, which may partly explain some of the clouding of consciousness and subsequent amnesia

Artificial respiration was given along the lines described by Crampton Smith et al (1956), a standard Radcliffe respirator being used For the most part the patients breathed ordinary air to which oxygen 0 5–1 0 litre per minute was added There was no indication for the use of nitrous-oxide anæsthesia once the tracheostomy was completed, indeed the dangers of aplastic anæmia following long-continued administration of this gas (Lassen et al 1956) strongly contraindicated such a procedure

Movements of the eyes and tongue were often noticed when the patient was otherwise completely paralysed and gave no indication of the need of more tubocurarine

Physiotherapy and Tracheobronchial Toilette

Pulmonary complications were fewer than was expected This appeared to be due largely to the postural drainage applied by an expert physiotherapist five times each twenty-four hours, and more often if required, and to the routine toilette of the tracheobronchial tree by at least half-hourly aspiration through a soft rubber catheter Undoubtedly the humidification of the inspired air (Marshall and Spalding 1953) and the fact that the foot of the bed was kept constantly raised were also important factors in this respect

The inevitable transient episodes of pulmonary collapse could be quickly detected by a rising pulse-rate, slight cyanosis, and a simultaneous decline in the respiratory minute volume unexplained by the need of more tubocurarine Re-expansion could readily be obtained by vigorous physiotherapy and aspiration Frequent chest radiography was of little value in view of the rapidity with which the chest condition altered

Specific Therapy

Antitetanic serum —Both patients were given large and often repeated intramuscular injections of antitetanic serum, each preceded by an oral anti-histamine drug No ill effects were detected, indeed the temperature and pulse-rate fell on several occasions a few hours after the injection

Reference must be made also to the dramatic deterioration in case 1 on the eleventh day of the illness

We have no doubt that she would have died at this time in peripheral circulatory failure if she had not responded to the noradrenaline infusion It is of interest that the penicillin given from the start of the illness had been stopped two days before this collapse, and no antitetanic serum had been given in the previous four days The child remained extremely ill with high fever (104 2°F) for eighteen hours until a further intramuscular injection of antitetanic serum 50,000 units was given Within four hours of this she rapidly improved, and shortly afterwards it became possible gradually to withdraw the noradrenaline infusion Though the possibility that this episode of profound toxæmia was due to *Staphylococcus pyogenes* septicæmia obtaining entry through the tracheostomy wound cannot be excluded, a true tetanus toxæmia, not relieved until more antitetanic serum was given, seems to us to be much more probable

Thus we cannot accept the view of various American authorities (Abel et al 1938, Dietrich 1940), who advise only a single injection of antitetanic serum, or of Spaeth (1940), who deprecates its use altogether Provided that a test dose produces no reaction and that each injection is preceded by an anti-histamine drug, the treatment of tetanus with large repeated intramuscular injections of serum is in no way superseded by the additional techniques here discussed, indeed it is still one of the sheet anchors of treatment Rapid desensitisation by multiple injections of increasing strength can be achieved if the initial test dose of serum gives a positive reaction

Antibiotics—Penicillin is clearly indicated as long as active signs of clinical tetanus persist Other antibiotics may be required to prevent respiratory complications

Excision of wound—When the wound was explored in both patients *Cl tetani* was isolated This fact re-emphasises the need to explore even the most trivial wound in every patient with tetanus

Fluid balance—It was possible for most of the time to give adequate fluids, electrolytes, vitamins, and a high-calorie diet by stomach-tube In both patients gastric function failed temporarily soon after the start of treatment with tubocurarine and I P P R Possibly cessation of normal diaphragmatic movement plays a part in this failure During this period large quantities of fluid had to be aspirated from the stomach, hence the electrolyte requirements had to be carefully watched and supplied

General Supervision

During the treatment of case 1 by I P P R a "shift" system was instituted by which a doctor was always present with the patient throughout the twenty-four hours, but during the treatment of case 2 by I P P R we relied instead on third-year student nurses, because we thought that the disruption of the work of a busy hospital which a shift system causes was unjustifiable These nurses gave all the routine treatment, including tubocurarine and tracheobronchial toilette, in a highly efficient manner A system of alarm bells was installed so that in an emergency medical help would be immediate, but this was never used

Active Immunisation

Finally, we emphasise that, in rural areas particularly, there is still a small but recurring morbidity and mortality from tetanus More widespread use of active immunisation in childhood in such areas is most strongly to be recommended

Summary

The detailed treatment of two children with severe tetanus by complete paralysis and intermittent positive-pressure respiration is described

These additional techniques in no way supersede the established forms of treatment—e g, large repeated intramuscular injections of antitetanic serum

Whatever recovery-rate may be achieved even in severe cases of tetanus, more widespread use of active immunisation in childhood, especially in rural areas, is strongly recommended

We wish to record our thanks to our colleagues who have been mentioned in the text, and also to Dr W J Walter, Dr G S Steele-Perkins, and Dr Butler, consultant anæsthetists, to Dr N S Alcock, consultant neurologist, and to Dr P C Gautier-Smith, resident medical officer, and to all the other members of the resident medical staff, all of whom were involved directly or indirectly in the care of these patients Our thanks are due also to Sister Ashby and the nurses, to the physiotherapists, and to Mr Berry, who maintained the apparatus

PERCUTANEOUS INTUBATION OF THE FEMORAL VEIN FOR TRANSFUSION

DAVID VEREL
M A, M D Cantab, M R C P
SENIOR LECTURER IN MEDICINE, THE UNIVERSITY OF SHEFFIELD,
HONORARY CONSULTANT PHYSICIAN, UNITED SHEFFIELD HOSPITALS
AND SHEFFIELD REGIONAL HOSPITAL BOARD

INTRAVENOUS transfusion is usually made through a suitable needle inserted into a vein of the arm or the leg When this method is unsuccessful or a prolonged transfusion contemplated, a vein may be exposed through a small incision and a cannula tied in Neither method is without disadvantages The use of a needle entails immobilisation of the limb, and thrombosis of the vein is a not uncommon sequel Further, when blood is given, the transfusion rarely runs for more than twenty-four hours Cannulation of the vein entails its ligation and ultimate obliteration Neither method can be used with safety for vesicants or strong dextrose solutions, and both may fail where profound shock is accompanied by intense constriction of the peripheral veins

The ease with which a small nylon catheter may be inserted into a vein in the arm (Verel 1954) suggested that a larger catheter might be of value for blood-transfusion Russell et al (1954) had used a polyethylene tube inserted into the femoral vein by cut-down in the management of anuria and found it remained patent for many days The femoral vein is easily punctured and had been used on several occasions for obtaining blood samples from severely shock subjects A technique was therefore devised for inserting a large catheter into the femoral vein through a suitable needle

Materials

Nylon tubing into which a standard blood-transfusion needle would fit was first obtained ('Portex' no 3 or 'Becton Dickinson' 0 65 in are suitable) Three sizes of stainless-steel tubes were then prepared

(1) A cannula 3 5 cm long fitting into the tubing easily but without leaks,

(2) A cannula 3 5 cm long fitting the tubing very tightly, and

(3) A needle through which the nylon tubing passed easily but not loosely (this was ground to a sharp bevel and fitted for convenience of handling with a Luer hub)

Method

The needles are dry-sterilised in individual glass tubes The nylon tubing is cut as needed and boiled in a bowl or autoclaved before use It should not be picked up with forceps when warm, because this may pinch it flat For most purposes a 20–25 cm length is used, one end is cut square and the other with a 45° bevel

A trolley is laid out with 3 sterile towels, 2 syringes of 5 ml capacity, several intradermal needles, a 5 cm 19-gauge needle, and ampoules of physiological saline solution, heparin, and 2% procaine solution A 5 ml syringe is first filled with physiological saline solution containing a drop or two of heparin and the small cannula is attached to it The square-cut end of the tubing is then threaded on to this, the cannula is filled with heparin-saline mixture, and the bevelled end is passed through the introducing needle to make sure that sterilisation has not affected the fit of the tubes (polyethylene tubing is unsuitable because it swells on boiling and tends to split when cannulæ are pushed into it) A second 5 ml syringe is then filled with 2% procaine, and a short intradermal needle is attached to it

The patient is then laid supine, with only the head raised on pillows (For orthopnœic patients the head of the bed is raised on blocks) The thigh on the side to be intubated is then abducted to about 45° to the trunk and everted so that it lies easily on the bed The pubic tubercule is then identified, and

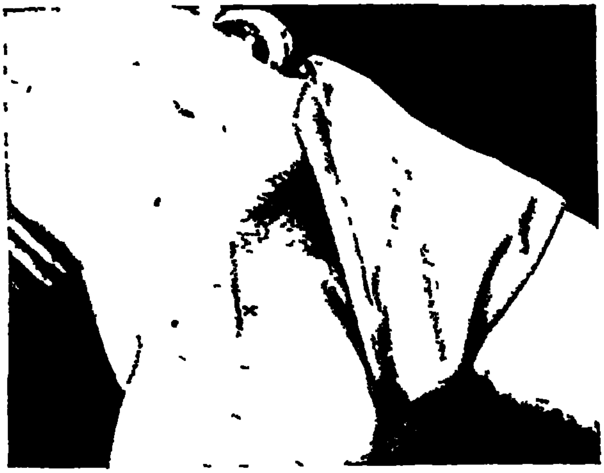

Fig. 1—Thigh positioned for intubation. Line of femoral artery marked with a skin pencil; cross shows approximate site for infiltration with local anæsthetic.

the course of maximal pulsation of the femoral artery is marked clearly on the skin from the point at which pulsation can be felt above Poupart's ligament to at least 12 cm. below it (fig. 1). Once this has been done, the patient's thigh is not moved until the transfusion is running.

A point is then selected 4–5 cm. below Poupart's ligament and 5–8 mm. medial to the line of maximal arterial pulsation. After the skin has been carefully cleaned, the skin and subepithelial tissues are infiltrated with about 2 ml. of local anæsthetic. The 5 cm. 19-gauge needle is then attached to the syringe and, through the same puncture, introduced at an angle of 45° to the skin, advancing upwards towards Poupart's ligament parallel to the artery but 5–8 mm. medial to it. Each time the needle-point encounters a fascial plane the advance is halted and the syringe held lightly to see if any transmitted pulsation indicates that the artery lies beyond the needle. If none is felt and aspiration yields no blood, 0.5 ml. of local anæsthetic is injected, and the needle is advanced to the next point of resistance until either the femoral vein is encountered or bony resistance is felt. If bone is encountered, the needle is carefully palpated to determine whether it has passed between the artery and vein or medial to the vein, and, after withdrawing the needle into the superficial tissues, a corrected direction is tried. Should the artery be entered by mistake, it is easily distinguished by the colour of the blood. Blood-pressure may be misleading because, if the patient is lying with the head of the bed raised, the pressure in the femoral vein is enough to force the plunger of the syringe out. Once the femoral vein has been identified, the angle and depth of the needle in relation to the line of the artery marked on the skin are carefully noted.

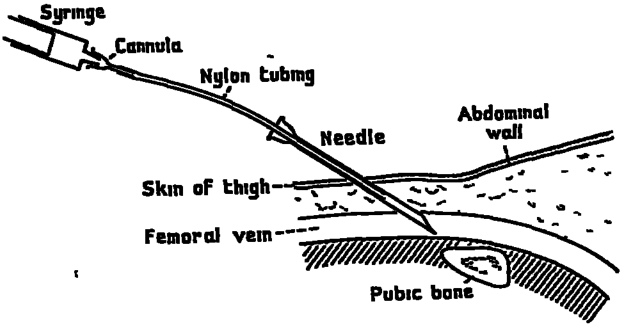

Fig. 2—Femoral vein pierced by introducing needle: point of needle lies within femoral vein, and nylon tubing is in needle and connected to syringe by easily fitting cannula.

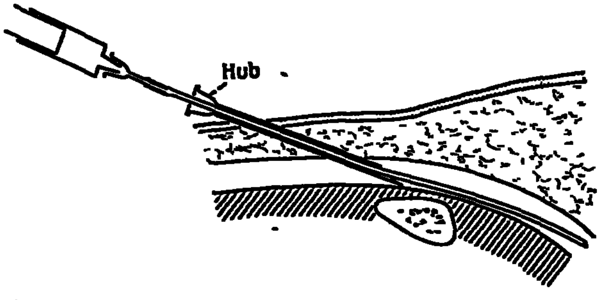

Fig. 3—Needle depressed until hub touches thigh, and tubing passed through needle until syringe and cannula are close to needle-hub.

Sterile towels are then applied so that only a small area round the site of the injection is exposed. An assistant prepares a transfusion set, attaching the large cannula to the nipple of the set. The catheter with attached syringe and introducing needle is now laid on the sterile towel and drawn back so that its tip lies within the introducing needle. The needle is then pushed through the skin at the site of the local infiltration, the needle being held in the line of the artery and almost parallel to the skin of the thigh because considerable force is needed to penetrate the dermis and, if this is attempted with the needle at 45°, all tissues down to the pubic bone may be suddenly transfixed. (Alternatively the needle may be introduced through a puncture made with a small tenotome.) The needle is then drawn back until only its tip is within the skin, and it is raised to 45°. The position of the artery is checked by palpation, and the needle is gently advanced until the first resistance is felt. If there is no transmitted pulsation and aspiration by the syringe on the end of the tube produces no blood, the needle is pushed on and the aspiration repeated. The sequence of advance, pause to check for pulsation, and then aspiration is repeated until venous blood is drawn into the tubing, indicating that the femoral vein has been entered (fig. 2). (Usually the vein wall causes moderate resistance, and the ease with which the needle can be advanced in the lumen of the vessel is recognisable.) The blood is then ejected from the tubing by

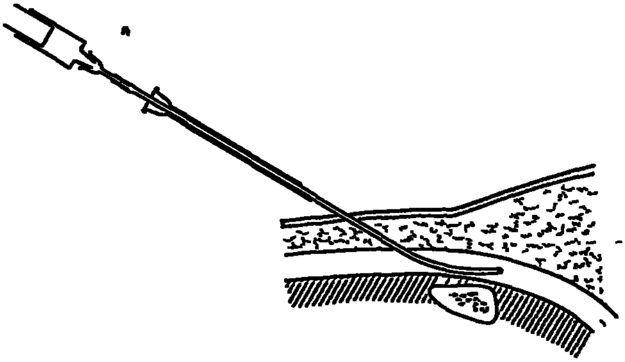

Fig. 4—Introducing needle withdrawn with syringe and cannula. Assistant now fixes tubing where it enters skin by firm pressure while cannula is withdrawn and needle removed.

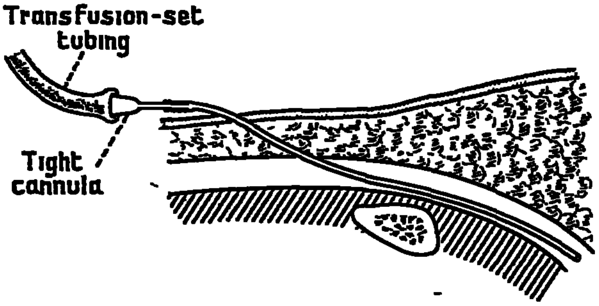

Fig. 5—Tightly fitting cannula connected to transfusion set is now inserted into nylon tubing, and transfusion is started. Nylon tubing is then pushed well up into vein, and cannula and transfusion-set tubing are taped to skin.

PATIENTS TRANSFUSED INTO FEMORAL VEIN

Case no	Duration of transfusion	Volume transfused	Nature of fluid	Diagnosis	Indication for use of tubing
1	3 days	7 pints	Blood	Hæmorrhage from œsophagus	Profound shock, no peripheral vein suitable
2	1 day	3 pints	Blood	Hæmolytic anæmia	No suitable vein remained
3	1 day	3 pints	Blood	Ulcerative colitis	Previous cut down, no suitable superficial vein
4	1 day	2 pints	Blood	Emphysema, peripheral circulatory failure	Profound shock, no peripheral vein suitable
5	6 days	20 pints	Electrolyte, glucose and packed cells	Anuria	Election
6	2 hr	1/2 pint	Saline solution and N_2 mustard	Hodgkin's disease	Previous thrombosis of forearm vein
	"	"	"		
	"	"	"		
	"	"	"		
	1 day	"	Saline solution, N_2 mustard, and blood 3 pints		
7	2 days	7 pints	Packed cells	Chronic gastrointestinal hæmorrhage, heart failure	Election
8	1 day	4 pints	50% glucose, electrolytes	Pulmonary tuberculosis, anuria following hæmorrhage	Election
9	8 hr	2 1/2 pints	Blood	Gastrointestinal hæmorrhage	Profound shock, no peripheral vein suitable
10	1/2 hr	100 ml	50% sucrose	Raised intracranial pressure	Poor peripheral veins
11	5 days	6 pints	Blood	Hæmatemesis	Election
		8 pints	Electrolytes	Pyloric stenosis	
12	12 hr	3 pints	Packed cells	Acute leukæmia	Election
13	12 hr	3 pints	Blood	Acute hæmorrhage	Profound shock
14	21 hr	2 pints	Blood	Postoperative transfusion	Election
		3 pints	Electrolytes		

injecting heparinised saline solution, the syringe being held so that any bubbles which may have entered are retained in the syringe

The tubing is now pushed gently forwards Sometimes the tube will pass easily up the femoral vein with the needle at 45° to the skin More usually, after advancing about 1 cm beyond the end of the needle, it sticks although aspiration reveals that it is still in the vein This arrest is probably due to the acute angle of entry. The tube is withdrawn a few mm and the needle-hub lowered to the level of the skin of the thigh, a single layer of sterile towel only separating the two In this position the tube is passed in until only 1 cm remains outside the introducing needle (fig 3)

The end of the tubing with the narrow cannula and the introducing needle are now gripped firmly, and the introducing needle is withdrawn until about 0 5 cm of the tubing is visible between the needle-tip and the skin (fig 4) An assistant then fixes this by firm pressure with a swab over the puncture The narrow cannula is now drawn out of the tubing and the introducing needle slipped off The tubing slides easily in and out of the skin puncture, so a careful watch at this stage must be kept to prevent the tubing from being completely pulled out with the needle During this manœuvre saline solution and then blood should flow freely from the catheter The large cannula is then connected and the transfusion started The nylon tubing may then be pushed into the vein (fig 5) The tubing of the transfusion set is taped to the skin in three places If blood still leaks from the site of entry, a collodion dressing is applied

At the end of the transfusion the catheter is removed and light pressure over the puncture is applied for one or two minutes. In all cases a nurse has been responsible for its removal

Note Two cannulæ are used because the large one is tight enough to dilate the nylon tubing slightly If this were used in the preliminary stages it would prevent the removal of the introducing needle at the end of the intubation

Results

Details of the first 18 occasions on which femoral-vein intubation was used are shown in the accompanying table Its use was originally restricted to patients in whom conventional methods were impossible, but it has proved so convenient that it is now preferred to both cut-down and simple transfusion with an intravenous needle in any patient in whom the transfusion is expected to run for more than twenty-four hours

The tubing has proved suitable for transfusing stored blood, packed cells, electrolyte and glucose solutions, and nitrogen mustard without mishap

The puncture in the femoral vein was identified in case 8, who died twenty-four hours after the transfusion was set up There was a clean hole in the intima without any surrounding thrombosis or any subcutaneous extravasation of blood

Three colleagues have used the method successfully on their own patients and prefer it to cutting down on a vein

Some difficulties have been encountered

In the first case in which the method was tried the catheter would not enter the vein, although the needle was apparently correctly placed. The patient was very obese, and the vein was punctured only when the introducing needle had entered up to the hub. A longer needle (9 cm) was made for use in such patients when it was realised that the acute angle of entry might cause the catheter to stick

In one patient the catheter slipped out of the vein during the removal of the introducing needle Careful fixing of the catheter by pressure where it enters the skin has prevented a recurrence of this mishap

In several instances during transfusion of blood the flow ceased On all of these occasions the tubing was patent, and the block was found in the transfusion set, except in one case where the transfusion stopped at another hospital and the site of the block was not identified

The longest transfusion in this series ran for six days The tubing may be used for much longer periods, however In one patient with anuria a similar transfusion was set up into an arm vein It was used for giving blood and solutions of dextrose and electrolytes for more than three weeks When the tubing was removed because it was no longer needed, there was no evidence of blockage or of venous thrombosis

7 patients who had previously been transfused by conventional methods were questioned by an independent observer after transfusion Five expressed a preference for the use of the femoral-vein intubation, one would express no preference, and case 2 had a strong dislike of the femoral-vein approach Since case 2 had been subjected elsewhere to twenty-five transfusions mostly by cut-down, no suitable vein remained Fortunately a remission in her hæmolytic anæmia made further transfusion unnecessary

The nurses preferred the use of the femoral vein because the patient retained the use of all four limbs, and all ordinary nursing care, including the use of the bedpan and blanket bathing, was possible, patients fed themselves and slept comfortably on their sides if they wished, no patient turned over on to the tubing in his sleep, because the firm attachment by sticking-plaster to the unshaven thigh woke them if they tried to do so The ease with which patients could be moved is well illustrated by 2 instances case 5 was transferred by ambulance for fifteen miles to another hospital, the transfusion being continued during the journey, and gastroscopy was performed on case 11 during transfusion

Summary

A technique for passing a nylon tube into the femoral vein through an intravenous needle is described The tubing has proved suitable for transfusing whole blood, packed cells, and solutions of electrolytes, glucose, 50% dextrose, and nitrogen mustards

No complications were encountered During transfusion the patients may move freely and may be transported by ambulance Gastroscopy was done on one patient during transfusion

The method is simple and provides a certain method of transfusion in severe shock, where venous spasm may render conventional methods ineffective It is now preferred to tying in a catheter and simple needle insertion in any patient in whom transfusion is expected to last more than twenty-four hours

RECURRENT FACIAL EMPHYSEMA

J A Black
M D Cantab, M R C P
PÆDIATRICIAN, RENFREWSHIRE

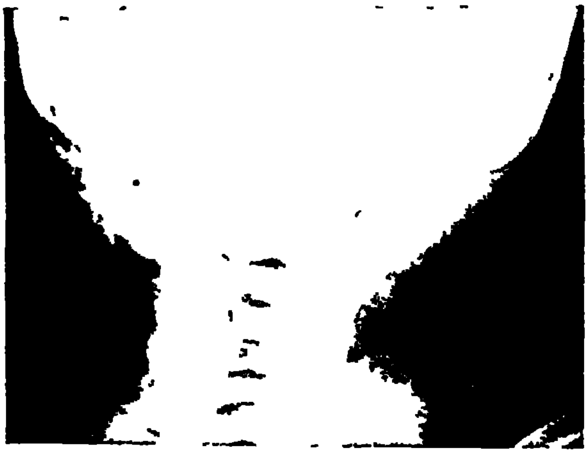
R P Lawrie
M B Glasg, D Obst
GENERAL PRACTITIONER, GREENOCK

EMPHYSEMA of the subcutaneous tissues of the face and neck usually results from a traumatic or surgical opening in the wall of the mouth, œsophagus, or respiratory tract Commonly the air reaches the face by upward spread from mediastinal emphysema or from extensive collections of air in the chest wall Emphysema confined to the face and neck is relatively uncommon and is usually a complication of tracheotomy, bronchography by the cricothyroid route, dental extractions or operations (Brown 1949), or puncture of the antrum

Spontaneous mediastinal emphysema is rare (Matts 1957) and spontaneous emphysema of the face even rarer, but Jackson and Jackson (1936) wrote "subcutaneous emphysema occurs spontaneously in a few cases probably the result of rupture of the mucosa of the upper air and food passages"

A curious type of facial emphysema was described by Reading (1950) under the title of "autemphysesis" a German prisoner-of-war produced extensive emphysema of the face and neck by means of a small incision on the inner side of the left cheek The patient stated that this could be produced by a razor-blade or by nipping the cheek between the molars Air was then forced into the tissues of the neck by expiration with the mouth closed and nose pinched between finger and thumb

Similar cases were observed during the Middle East campaign, and a medical directive was sent out to warn medical officers to look out for these cases, which presented like mumps



Emphysema of subcutaneous tissues on right side of neck.

In the case described here we could not find any cause for the emphysema, and we publish the case partly because of its intrinsic interest and partly because we hope that others may be able to explain the recurring emphysema

Case-report

A girl began, at the age of $8^1/_2$ years, to have episodes of swelling of the face During the first attack she was thought to have mumps, but the recurrence of the swelling at intervals of about a fortnight excluded this diagnosis The swelling affected either side of the face but only once occurred simultaneously on both sides, and seldom lasted more than two or three days The swelling was greatest over the parotid region in the first attacks There was no pain, but the girl occasionally complained of discomfort in the ears and of "crackling in the gums" The significance of the crackling sensation was not appreciated until the correct diagnosis had been made The attacks always came on when she was upset at school, which she did not like Apart from this there was no indication of a possible cause of the swelling

On Aug 11, 1956, at the age of 9 years, she was referred to the pædiatric outpatient clinic at the Greenock Royal Infirmary At this time there was no swelling, and recurrent parotitis was provisionally diagnosed The regions of the parotid glands and ducts were radiographed, but no calculi were found In view of the absence of any residual enlargement of the parotids and in view of the painlessness of the swelling during the attacks, the diagnosis of recurrent parotitis did not seem wholly satisfactory, and it was suggested that she should be seen again when the swelling was present

She was seen at her home on Oct 2, 1956, when she had a swelling of the right side of her face, mainly in the parotid and infraorbital regions Pressure over the parotid gland did not cause pain Pressure on the inner side of the right cheek produced the crackling sensation of subcutaneous emphysema, and this was also present over the parotid gland and in the upper part of the neck A search was made for a lesion of the inner surface of the cheek, but none was found The gums and teeth were healthy, and there had been no recent dental extractions Radiography of the face, neck (see figure), and chest showed that the air was confined to the face and upper part of the neck on the right side There was no evidence of mediastinal emphysema or of pneumothorax

Later, when the swelling had subsided, the girl's teeth were examined, and Mr Ian Munro examined her ears, nose, and throat No abnormality was discovered, and radiography of her sinuses, maxillæ, and lower jaw was also quite normal

Discussion

The only clue to the cause of the emphysema was the association between emotional tension at school and the onset of swelling Since the child did not like her school, it seemed possible that she might be producing emphysema either deliberately or involuntarily while crying An accidental or deliberate puncture of the buccal mucosa with pen-nibs or pencil was denied, and the mother stated definitely that the swelling was not associated with crying Finally, an attempt to reproduce the emphysema by getting the girl to inflate a balloon did not cause any swelling of her face

During the following weeks she continued to have recurrent attacks of emphysema when she was upset at school In November, 1956, the Education Committee was asked to change her school When last seen in October, 1957, she had started at her new school and was quite happy Since her change of school she has had one brief episode of the emphysema due to coughing during an attack of influenza

There was thus no discoverable mechanical cause for the emphysema and no explanation for its association with emotional tension or for the appearance of the swelling on either side of the face

Preliminary Communications

THE EFFECT OF HUMAN GROWTH HORMONE IN MAN

THE metabolic effect of growth hormone (GH) has been extensively studied in animals[1] In contrast, very little is known about the significance of GH in man GH purified from animal pituitaries has been used in metabolic studies in man, but the results obtained were either negative or inconclusive[2] It was shown later by Li and Papkoff[3] that GH purified from human pituitaries differs in chemical structural properties from the hormone purified from animal glands, and the behaviour of animal GH in man could be explained on this basis

TABLE I—RESULTS OF BIOLOGICAL ASSAY OF HUMAN GROWTH HORMONE

Preparation	Total dose (µg)	No of assay rats	Average tibia width* (µ)
84/57	20	5	190±5 3
84/57	80	5	226±6 7

* Mean ± standard error

In this communication we report preliminary results of metabolic studies on two volunteers given GH purified from human pituitaries Case 1 was a 35-year-old male, who had for many years suffered from rheumatoid arthritis, which had been clinically inactive for at least 8 years Case 2 was a male of 45, who had previously been treated for obesity His body-weight for the past three years had been 92 kg , and his height 185 cm

The metabolic studies involved standard procedures, using four-day collection periods for fæces and daily ones for urine

GH was given intramuscularly in a single daily dose of 10 mg , case 1 received injections for 12 and case 2 for 16 days

TABLE II—CUMULATIVE BALANCES OF NITROGEN, PHOSPHORUS, POTASSIUM, AND CALCIUM DURING ADMINISTRATION OF GROWTH HORMONE

—	Case 1	Case 2
Given GH for	12 days	16 days
Nitrogen balance (mg)	+40284	+40320
as protein in protoplasm (g)	252	252
as fat-free protoplasm (g)	1289	1290
Phosphorus balance (mg)		
calculated from nitrogen	+ 2686	+ 2688
actual balance	+ 2116	+ 2032
net balance (in relation to nitrogen)	− 70	− 656
Potassium balance (mEq)		
calculated from nitrogen	+ 109	+ 109
actual balance	+ 302	+ 186
net balance (in relation to nitrogen)	+ 193	+ 77
Calcium balance (mg)		
urine	− 888	− 720
fæces	+ 1572	− 1216
Total	+ 684	− 1936

Preparation of Growth Hormone

GH was purified from lyophilised human pituitaries, collected at necropsy, according to the chromatographic method of Li and Papkoff[3] The hormone content of the material was estimated qualitatively and quantitatively by zone electrophoresis on starch, and it was assayed biologically in hypophysectomised rats by the tibia test[4] (see table I).

When the GH preparation was submitted to zone electrophoresis on starch in a veronal buffer (0 01 M hydrogen veronal, 0 04 M sodium veronal, and 0 06 M NaCl) of pH 8 3 it migrated as a single protein No material remained stationary at the origin The GH preparation was easily dissolved in saline after adjusting the pH to around 7 0

RESULTS

Protein metabolism—The cumulative balances of nitrogen, phosphorus, and potassium during the treatment period are shown in table II In both patients a positive balance was obtained for all three elements The nitrogen retained in both corresponded to about 1 3 kg of fat-free protoplasm Potassium was retained in excess of the figure calculated from the nitrogen balance, while the phosphorus retained largely corresponded to the calculated amount The excess potassium corresponds to 1 3 and 0 5 kg of "wet glycogen" in case 1 and 2 respectively

Calcium balance (table II) —In both patients the urinary excretion of calcium increased The fæcal excretion of calcium, on the other hand, changed in opposite directions in these patients

Sodium and chloride balances (table III) —Both patients retained sodium and chloride, and increased their extracellular fluid volume as measured by the volume of distribution of chloride Both sodium and chloride were

TABLE III—CUMULATIVE BALANCES OF SODIUM AND CHLORIDE AND CHANGE OF THE CHLORIDE SPACE DURING ADMINISTRATION OF GROWTH HORMONE

—	Case 1	Case 2
Given GH for	12 days	16 days
Chloride space (litres)	+1 8	(+1 0)
Sodium balance (mEq)		
calculated from chloride space	+261	+145
actual balance	+397	+328
net balance (in relation to chloride space)	+136	+183
Chloride balance (mEq)		
calculated from chloride space	+180	+100
actual balance	+252	+144
net balance (in relation to chloride space)	+ 72	+ 44

retained in excess of the retention calculated from the change in extracellular volume It should be mentioned that in both patients perspiration increased during the treatment period

The rapidity of the changes in the balances induced by GH administration and withdrawal is illustrated in fig 1

Other metabolic effects—In case 1 there was a striking increase in the urinary excretion of acetone, and a disappearance of a pre-existing creatinuria (fig 2) Discontinuation of the hormone was followed by a return of acetone excretion to the pretreatment level, while the creatine excretion increased far above the level of the control period

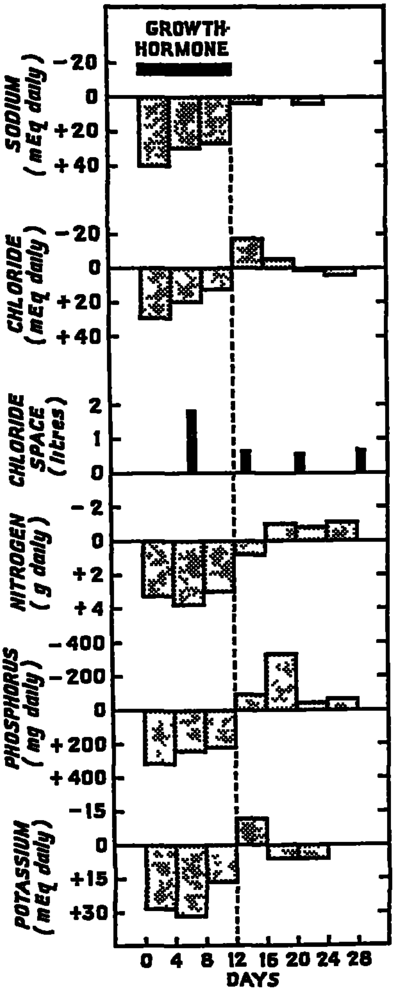

Fig 1—Changes in the balances of nitrogen, phosphorus, potassium, sodium, and chloride and the volume of distribution of chloride during and after administration of growth hormone in case 1

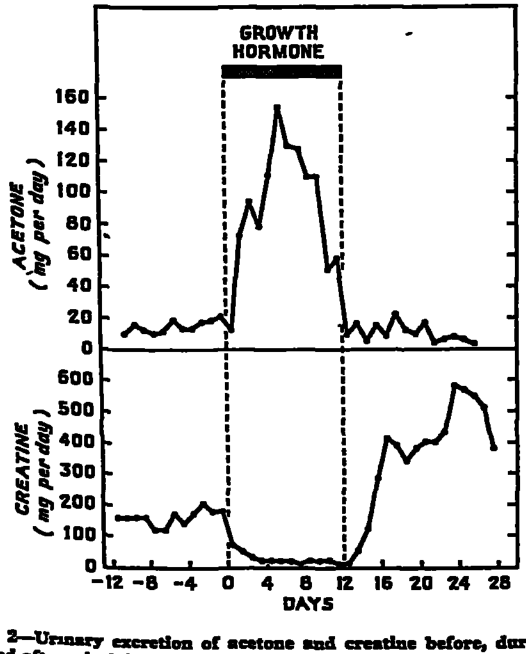

Fig 2—Urinary excretion of acetone and creatine before, during and after administration of growth hormone in case 1

In case 2 the creatine excretion was normal, and did not change, nor did the excretion of acetone change during GH administration The plasma levels of inorganic phosphate as well as of sodium, potassium, chloride, and calcium were unaffected by the hormone

Clinical effects—Both patients, especially case 1, showed increased perspiration, transient nervousness, and tachycardia as well as a feeling of satiety Furthermore, their daily consumption of water increased and the urine volume decreased No rise in temperature was noted, and blood-pressure remained unchanged There was no reaction at the site of injections

SUMMARY

Growth hormone purified from human pituitaries had a pronounced metabolic effect in two human subjects A daily dose of 10 mg produced retention of nitrogen, phosphorus, and potassium, retention of sodium and chloride together with an increase in the extracellular space, and increase in the urinary excretion of calcium In one of the subjects the excretion of acetone in the urine increased greatly and the creatine excretion, which was abnormally high, fell to normal during the hormone administration

EFFECT OF HUMAN GROWTH HORMONE IN HYPOPHYSECTOMISED DIABETIC SUBJECTS

THE "diabetogenic" effect of pituitary growth hormone (GH) in animals has been well documented[1-3] but very little is known about this "diabetogenic" effect in man GH purified from animal pituitaries has been used in metabolic studies in man, but the results obtained were either negative or inconclusive[4] It was shown later by Li and Papkoff[5] that GH purified from human pituitaries differs in chemical and structural properties from the ones purified from animal glands

In the previous communication[6] we showed that human GH was metabolically active in man In order to investigate the "diabetogenic" action of human GH, its effect on three hypophysectomised patients with diabetes mellitus was studied

The patients were a 35-year-old male (case 1) and two females aged 28 and 25 years (cases 2 and 3) All three had been hypophysectomised for about four, three and a half, and three and a half years respectively because of severe vascular complications (retinopathy, nephropathy, and neuropathy) Case 1 was receiving at the time of the present study a standardised diet and 48 I U of insulin Leo retard Cases 2 and 3 were studied under the conditions of a complete metabolic study The insulin requirements were 24 I U 'Novolene' for case 2

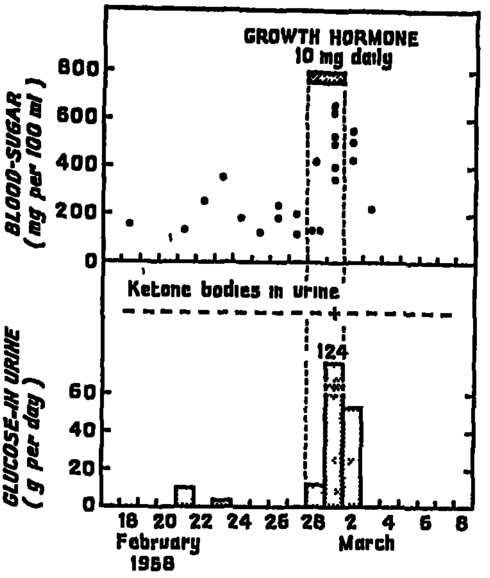

Fig 1—Blood-sugar level and urinary excretion of acetone and glucose in case 1 before, during, and after administration of growth hormone

and 24 I U protamine zinc insulin for case 3 Their remaining substitution therapy was as follows

	Case 1	*Case 2*	*Case 3*
Cortisone (mg per day)	50	25	25
Thyroid extract (mg per day)	120	120	120

The GH used was prepared as previously described[6] Biological assay in hypophysectomised rats by the tibia test[7] gave the following results

Preparation	*Total dose (μg)*	*No of assay rats*	*Average tibia width* (μ)*
325/58	25	4	219 ± 10 1
325/58	100	4	279 ± 12 2

* Mean ± standard error

The GH preparation was easily dissolved after adjusting the pH to about 7 0 GH was administered in a daily dose of 10 mg at 8 A M The duration of administration is shown in figs 1–3 No fever or local reaction at the site of injections were observed

RESULTS

In cases 1 and 2 (figs 1 and 2), the administration of growth hormone was followed immediately by a deterioration of the diabetic state as demonstrated by the increase in blood-sugar level and the appearance of pronounced glycosuria and ketonuria Because of the deterioration of the patients' condition, extra insulin had to be given in both cases 36 hours after the first injection of GH, the administration of which had to be discontinued In case 2, GH was given again 12 days later, and the same effect on carbohydrate metabolism was obtained

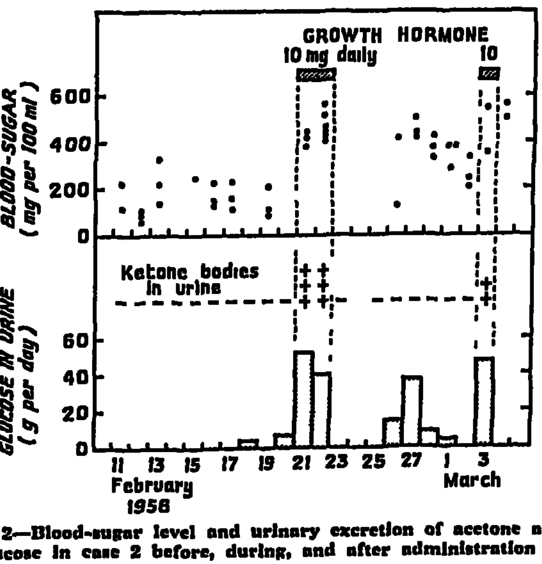

Fig 2—Blood-sugar level and urinary excretion of acetone and glucose in case 2 before, during, and after administration of growth hormone

The effect of GH in case 3 (fig 3) was similar though less pronounced Glycosuria and blood-sugar concentration increased during the first 24 hours, but pronounced ketonuria did not appear as promptly as in the other two cases On the other hand, even here the administration of GH had to be stopped on the eighth day because the patient's general condition had deteriorated so much

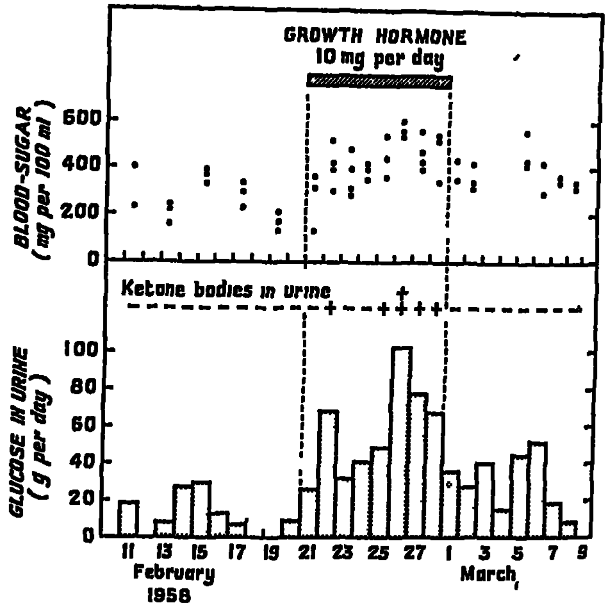

Fig 3—Blood-sugar level and urinary excretion of acetone and glucose in case 3 before, during, and after administration of growth hormone

SUMMARY

Growth hormone purified from human pituitaries was administered to three hypophysectomised diabetic patients In all three the hormone administration was followed by a pronounced increase in blood-sugar level, glycosuria, and acetonuria In two of the patients, the administration had to be stopped after 36 hours

New Inventions

MODIFICATIONS OF A SPIROMETER FOR TIMED CAPACITY AND MID-EXPIRATORY FLOW MEASUREMENTS

THE percentages of the total vital capacity expired in 1, 2, and 3 seconds indicate the degree of obstructive impairment of ventilation (Gaensler [1]) Leuallen and Fowler [2] have shown the additional value of measurement of mid-expiratory flow-rates in early emphysema We describe here a simple modification of a spirometer in general use, which records the total vital capacity and any volume expired during a pre-set time-interval of 0 1–3 0 sec (in a similar fashion to the modification described by Gaensler) but in addition permits easy and rapid calculation of flow-rates from the start of mid-expiration

The only alteration to the ordinary spirometer is the insertion of a pin into the top of the counterweight to project horizontally through the slot in the counterweight cylinder The extra attachments (see figure) are

(1) A solenoid mounted on the bracket supporting the recording disc, in such a way that its rod holds the pointer When the solenoid is energised from the timer, the rod is raised and the pointer released

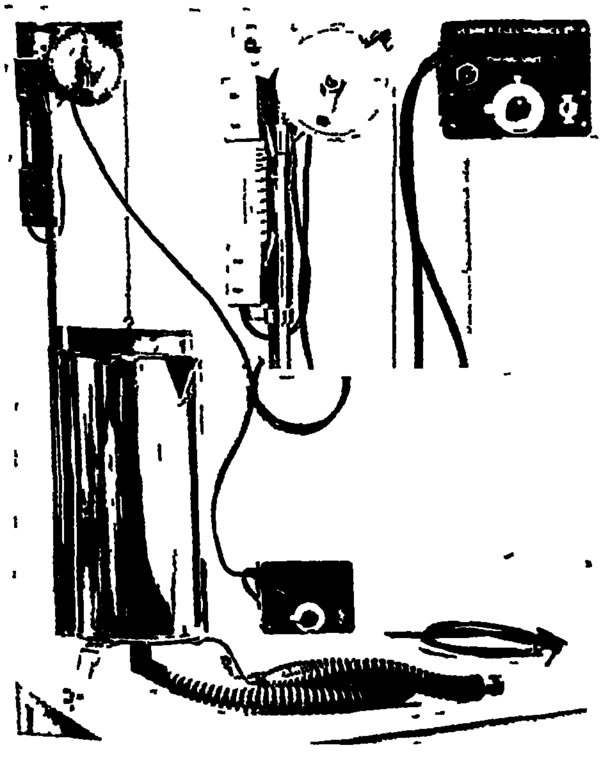
(2) A fixed microswitch mounted above and to the side of the counterweight and kept open, when the counterweight is at its highest position, by the counterweight pin

(3) A second microswitch, mounted on the side of the counterweight cylinder, can be moved on a scale calibrated downwards from 0 to 1600 c.cm

(4) A third switch, mounted above the fixed microswitch, determines which of the two microswitches is brought into operation

(5) An electronic timer graduated from 0 1 to 3 0 sec can be energised by a momentary electrical impulse

The end of the bracket supporting the recording disc acts as an indicator for the total vital capacity For timed capacity, the timer is set to the interval required, and the fixed microswitch is brought into operation As the spirometer bell rises, the counterweight descends, its pin closes the microswitch, and the timer is actuated The pointer is held until it has registered the amount expired during the set interval, after which the solenoid rod is raised and the pointer released to travel round with the disc For flow-rates from the start of mid-expiration, the movable microswitch is brought into operation and is then set to a position on the scale corresponding to a quarter of the total vital capacity This amount is therefore expired before the counterweight pin closes the microswitch Consequently the pointer registers the first quarter of the vital capacity together with the amount expired during the interval, after the first quarter, for which the timer is set (0 1–3 0 sec) By subtraction of the quarter of the vital capacity it is easy to calculate flow-rates from the start of the mid-expiratory phase



Timed capacity could, of course, be estimated solely by setting the movable microswitch to 0 on its scale On this machine two microswitches have been included to avoid having to set the movable microswitch to 0 after every estimation of mid-expiratory flow, and to avoid repeated settings of it, if it is desired to estimate the value of timed capacity after the expiration of certain fixed amounts

This modified spirometer is proving of use as an aid to clinical assessment, but it is hoped that its main value will be in the early diagnosis of emphysema and estimation of its progress, by enabling routine serial observations to be made on patients under supervision with chronic chest disease. Its simplicity of operation is a great advantage in outpatient work, where observations have to be made on many patients in a short time At this clinic health visitors have been trained in its use and make most of the estimations As it is an adaptation of equipment already in use, unnecessary expenditure has been avoided

The modifications were made by Messrs Venner Electronics, Ltd, New Malden, Surrey, and our thanks are due to Mr D R Ollington for his help

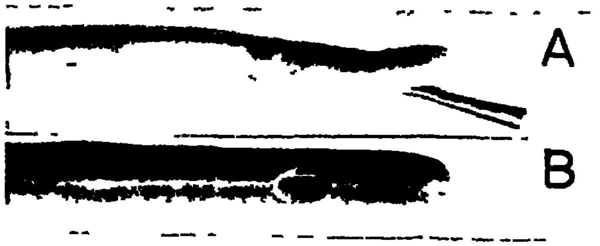
A MODIFIED FOLEY CATHETER

THE soft latex-rubber Foley self-retaining catheter is probably the most popular instrument for continued drainage of the bladder, but, unfortunately, in some cases its pliability makes its passage through the prostatic urethra impossible



To overcome this difficulty, a metal introducer is often used but, with the standard pattern of catheter, the tip of the introducer easily slips through the eye of the catheter and may injure the urethra (see figure, A)

A minor but useful modification of the catheter is shown in the figure, B In this pattern the eyes of the instrument are receded 2 cm from its tip, the end of the introducer sits comfortably within the cul-de-sac so formed without risk of displacement and can be used with complete safety

The catheter was made for me by Messrs Wm Warnes and Co and is a modification of the Warnes balloon catheter I wish to thank Mr E L Tugwell for the photograph

Reviews of Books

An Introduction to Chest Surgery

GEOFFREY FLAVELL, F R C S , M R C P , thoracic surgeon, The London Hospital London Oxford University Press 1957 Pp 354 30*s*

THE rapid advance of chest surgery has made many books on this subject out of date before they are published, and it is hard to find one which can give the student and practitioner as distinct from the expert) an accurate picture of current practice

Mr Flavell and his publisher are to be congratulated on providing in this book the maximum information at the minimum cost The approach is practical, and after short ntroductory sections the author embarks straightway on how to look at a chest X ray, bronchoscopy, and pulmonary resections

The various conditions which may call for surgery are concisely discussed, and a number of short case-histories are added, to show how errors in diagnosis and treatment can arise and how they should have been avoided In the discussion on the diagnosis of bronchial carcinoma Mr Flavell points to an important fact even as recently as 1954 there was an average delay of over eight months between the first symptoms and surgical removal of the growth, and only one to two months' delay could be attributed to the patient Apart from diseases of the lung, there are adequate sections on the œsophagus and heart which discuss those conditions that can be treated surgically The final chapter, on mitral stenosis, is an admirable description of the disease and its possible remedy Clear line drawings and several pages of small but good X-ray reproductions illuminate the text

Here and there are matters about which other thoracic surgeons might disagree, but the balance of the book and its easy style should make it very acceptable to the general reader It gives an excellent picture of the scope of surgery in thoracic disease and provides much information that is not readily found in general medical and surgical textbooks

The Dynamics of Anxiety and Hysteria

H J EYSENCK, PH D , professor of psychology, University of London London Routledge & Kegan Paul 1957 Pp 312 32*s*

FROM time to time Professor Eysenck summarises in a book the work of his group at the Institute of Psychiatry (Maudsley Hospital) His latest instalment begins with a recapitulation of earlier work seeking to show that psychotic patients can be distinguished from those who are neurotic by their scores in a battery of objective tests, and that by further tests neurotic patients can be subdivided not only by their measurable degree of neuroticism or emotionality but also by their degree of introversion or extroversion Thus, hysterical patients are more extroverted than persons with anxiety states Professor Eysenck then passes on to a detailed analysis of the observed differences in learning, perception, socialisation, and response to drugs shown by the different personalities he has defined He measures the ease of acquisition or extinction of conditioned reflexes involving eye blinking, the rate of dark adaptation, attitudes to divorce and the death penalty, and nonsense-syllable learning while under the influence of amylobarbitone or dexamphetamine, and he interprets the results in terms of a neo-pavlovian theory of cerebral excitation and inhibition

The book is not easy reading Its chief value lies in its discussion of the experimental methods used, and the references to the fuller published papers of the Eysenck school The theory it proposes is still evolving, and unfortunately it appears so far to be moving along a different dimension from clinical psychiatry The author himself admits that it seems oversimple to explain the phenomena of hysteria and anxiety It must be added that the results on which it is based are statistical correlations between items of behaviour of groups of people Measurement of items of behaviour of an *individual*, with quantitative prediction of *his further* responses, is what interests the clinician, and general statements of probabilities in groups are of little use Professor Eysenck's ideas, however, have already stimulated a good deal of experimental work, and will provoke more, and that is sufficient justification for a scientific hypothesis If they could be applied longitudinally instead of cross-sectionally (that is, if the measurements were repeated at different times in the life of the same individual) they might come to have practical relevance

Bone Tumours

DAVID C DAHLIN, M D , consultant, section of surgical pathology, Mayo Clinic, Rochester, Minnesota Springfield, Ill Charles C Thomas Oxford Blackwell Scientific Publications 1957 Pp 224 87*s* 6*d*

THIS is a study of 2276 consecutive bone tumours seen at the Mayo Clinic and no praise could be higher than that Dr Dahlin has done justice to such a rich source of material Anybody writing on bone neoplasms must come to terms with several problems to which there are as yet no satisfactory solutions Perhaps because there is often little correlation between the clinical course, histological structure, and radiological appearance of these growths, clinicians, pathologists, and radiologists have not yet agreed on a mutually acceptable nomenclature and without a common language it is hardly surprising that they have evolved no satisfactory classification Dr Dahlin bases his on a system suggested by Liechtenstein this has many features in common with Thompson and Turner-Warwick's classification and will be acceptable to most pathologists in this country The cell type is used as the chief criterion in assigning a tumour to its group this makes for histological accuracy, but it does not always favour clear distinction between what is clinically innocent and what is malignant

Tumours arising from marrow elements have been included in the survey malignant myelomas are, in fact, the largest single group The scope of the investigation can be judged by the fact that no less than 88 chordomas have been examined and analysed The lay-out and presentation of this vast material is impeccable and the illustrations have been judiciously selected and beautifully reproduced Dr Dahlin reaches no startling conclusions, but as a basis for further study his book will prove invaluable

Gastro-intestinal Obstruction

MEYER O CANTOR, M D , M S , F A C S , assistant attending surgeon, ROLAND P REYNOLDS, M D , F A C S , chief of surgery, Grace Hospital, Detroit Baltimore Williams & Wilkins London Baillière, Tindall & Cox 1957 Pp 565 144*s*

EVERY conceivable aspect of intestinal obstruction is here covered in a monograph by expert authors In a sapient preface they observe that, despite advances in the control of blood-chemistry by infusion and of infection by antibiotics, the mortality of obstruction can be reduced only by earlier operation

Starting at the œsophagus, they discuss obstruction at various levels of the alimentary tract Chapters follow on obstruction in special circumstances—in pregnancy, in infancy, and in the aged, for example—and then on procedures diagnostic, therapeutic, and operative The work would have been more effective if it had been more concise Emphasis is sometimes lacking, and it is hard at times to hold the thread Nevertheless as a source of information, with nearly 40 pages of bibliography (and over 40 references on each page), it excels

Air Pollution (London Butterworth 1957 Pp 248 42*s*) —As Sir Hugh Beaver says in his foreword, "The question of Air Sanitation is one that affects the country from the social, medical and economic points of view, but it is essential that its consideration should be put on to a technical and scientific basis rather than an emotional one" A conference held at Sheffield University in September, 1956, sought to do this, and the papers (here edited by Prof M W Thring) discussed the nature, measurement, sources, course, consequences, and elimination of air pollution Dr John Pemberton gives an account of the ill effects of air pollution on health and vegetation.

THE LANCET

LONDON 5 APRIL 1958

The Twist of the Cord

No surgical emergency is more commonly misdiagnosed than torsion of the spermatic cord to suggest that 70% of twisted testes are lost because of delay in diagnosis may be a charitable underestimate Whether such charity is deserved is another matter The condition is eminently treatable when recognised in time, and the fact that patients with unilateral testicular atrophy do not usually realise that they are the victims of medical error is hardly a source of comfort

Torsion of the spermatic cord is uncommon (though not nearly so uncommon as hospital records would indicate), and it might be argued that little time can be devoted to it in undergraduate teaching But too much, not too little, is usually said It would be preferable to impress on the student simply that any painful swelling in the scrotum, or any scrotal swelling with abdominal pain, should be treated as a case of torsion unless some other cause is definitely established, and to add a word of warning about undescended testes Torsion conforms to no classical picture, nor are there characteristic features by which it can be excluded Many textbooks still maintain that the onset is usually sudden, but this is by no means so In a series of 31 patients, seen between 1943 and 1956 at the Radcliffe Infirmary, Oxford, SMITH[1] found that the symptoms had struck suddenly in only 14, and in 7 the first complaint had been dull abdominal or loin pain Such referred pain is a common diagnostic pitfall, and it is not confined to cases of incomplete descent Testicular pain is often felt at a point occupied by the testis in embryonic life—especially in the region of the internal inguinal ring[2]—and inflammation of the tunica vaginalis can simulate intra-abdominal peritonitis In the Oxford series strangulated inguinal hernia had been diagnosed in 5 cases, appendicitis in 2, and perforated duodenal ulcer in 1 Indeed, only 6 of the 31 cases had been diagnosed correctly before admission, and SMITH adds, in all fairness, that " the misdiagnosis [had been] several times accepted after admission "

The commonest, and in many ways the most calamitous, error is to diagnose acute epididymo-orchitis, and it is therefore not surprising that surgical teachers should concentrate on the differential features of these two conditions That such differences exist cannot be doubted, but it is debatable whether more harm or good is done by relying on them in everyday practice Mild trauma sometimes precedes torsion, and it may seem reasonable to postulate a mechanical cause of a mechanical disorder Yet this is in fact one of the armchair notions that prevent earlier diagnosis Life is marked by an uninterrupted succession of trivial injuries, and it is almost fatuous to name such pursuits as gardening or playing football as possible predisposing causes 2 of SMITH's cases were in jockeys, but neither of them had ridden during the twenty-four hours before the onset of symptoms In a 3-day-old baby who was known to have had torsion at birth " it was difficult to see any possible cause other than fœtal movements in utero " In 8 of his patients torsion started during sleep[1] Moreover, sudden physical strain, and a rise of pressure in the posterior urethra, has not yet been exonerated as a precipitating cause of acute non-specific epididymo-orchitis Slightly more valuable, though neither positively nor negatively diagnostic, is a history of previous warning episodes—sometimes only momentary and often amounting to no more than a " niggle " or a " twinge " However trivial these may seem, it is difficult to condone such terms as " cremasteric colic " or " testicular neuralgia ", even true anxiety symptoms are rarely referred to the scrotum Patients with recurrent subacute torsion form another small but characteristic group Occasionally the patient's age is of diagnostic help Epididymo-orchitis is exceedingly rare—and mumps orchitis practically unknown—before puberty, while torsion respects no age All observers agree that the peak incidence is between 13 and 20 years,[1 3-6], but middle-aged and elderly cords have been known to twist, and infants are frequent sufferers In a survey of 30 cases, seen at four Edinburgh hospitals in 1948–54, ROBB[7] records that 9 were between 15 and 20, 8 under 5, and 6 over 20, and SCOTT[3] mentions a 53-year-old patient who had had attacks of testicular pain at about two-yearly intervals since the age of 15 These workers note the absence of urinary symptoms before torsion, but such symptoms are not at all common in the early stages of epididymo-orchitis

Occasionally torsion can be diagnosed at a glance or by the lightest touch Far more often it is indistinguishable with complete certainty from epididymo-orchitis, and if the patient is to be treated conservatively nothing less than complete certainty is permissible Several eponymous physical signs bear witness to the clinical acumen of their originators—and to the difficulties they had themselves experienced The sign perhaps most widely known—that elevation of the affected testis tends to relieve the pain of epididimytis but to aggravate the pain of torsion[8]—may have statistical validity, but it would be most unwise to base on it alone a negative diagnosis SMITH[9] suggested that, for easier palpation, the cord should be infiltrated with local anæsthetic and OGILVIE[10] found diagnostic aspiration of the secondary hydrocele helpful But infiltration abolishes the patient's subjective response to pressure, and the characteristic bloodstained effusion in the tunica vaginalis may be slow to accumulate And there is the greatest urgency if the testis is to be saved " if you let slip time ", MILTON observed in a different context, "like a neglected rose it withers on the stalk" [11]

In a densely populated country it should be possible to send every patient to hospital on the slightest suspicion, thus giving surgeons a chance to operate immediately *Manual* untwisting is still recommended by some as a possible alternative [12, 13], but, though the method scores an occasional success, the successful performer is usually the patient rather than the doctor After several subacute episodes some men acquire a knack in this manœuvre, and the medical amateur will be most unwise to persist in his efforts once the expert has failed Time is better spent in arranging for the patient's *immediate* transfer to hospital For the journey all he needs is a sedative and a suspensory bandage, to apply hot-water bottles—as is done often by patients, and occasionally by doctors—is as irrational as warming the limb threatened by gangrene If in hospital the diagnosis is confirmed, or if doubt persists, the scrotum must be explored Conservative treatment has been advocated for infants, on the questionable ground that in them the diagnosis is always late [14], and some surgeons feel that conservatism is justified in old people Unfortunately, in the elderly torsion is liable to progress to septic necrosis and gangrene For the patient the operation (which can be performed under local anæsthesia) is trivial From the surgeon it requires scrupulous asepsis, gentleness, and a thorough knowledge of normal and abnormal scrotal anatomy The majority of torsions affect abnormal testes, and even normal landmarks may be obscured by swelling and congestion

The most important anomaly in the ætiology of this disorder is complete investment of the testis and epididymis by a capacious tunica vaginalis [15-17], or the whole scrotal contents may lie free within the scrotum, resembling the condition described in normal infants by ASTLEY COOPER [18-20] In G I SMITH's series of the 25 cases in which the site of torsion was recorded it was extravaginal in 22, and (contrary to the opinion of earlier workers [21]) there is little doubt that the first two centimetres above the tunica vaginalis is the segment most commonly involved Rarely the testis rotates around an abnormally long or mobile mesorchium, and multiple twists have been described [22] Testicular torsion (in both its acute and recurrent subacute forms) may be indistinguishable clinically from torsion of a *hydatid of Morgagni* In the latter disorder at operation the greatly enlarged plum-coloured appendage can be a perplexing finding, but the surgeon must not rush into an unnecessary *orchidectomy* Also hard to diagnose is the rare case of testicular rupture and here too excision of the prolapsed tissue and suture of the tunica albuginea (rather than removal of the organ) may be the best course to follow [1]

Earlier workers laid stress on the prevalence of torsion in undescended testes SCOTT concluded that "approximately 50% of cases of torsion occur in cryptorchids, and, as the undescended testis is found in only about 0-2% of all men, this is a predisposing factor" [8] Greater awareness of scrotal torsion will almost certainly lead to revision of such estimates [23, 24] The complication may be slightly commoner in incompletely descended testes, but only in proportion to the frequency of incomplete descent, and some of the difference may be due to the fact "that one of the common misdiagnoses is strangulated inguinal hernia, a condition calling for immediate operation which reveals the true state of affairs" [1] Malignant tumours of the testis account for many intra-abdominal torsions [25], nor is this association unknown in the fully descended organ [26, 27] Another disputed feature of this condition is its alleged right-sided preponderance [28] The distribution was approximately equal on the two sides in ABESHOUSE's and in G I SMITH's series, and SMITH feels that there is "no good reason why one side should be affected more often than the other" It may be worth recalling, on the other hand, that congenital herniæ and incompletely descended testes are commoner on the right than on the left side

When the testis is viable some form of fixation is the obvious procedure of choice [29] When viability is in doubt it may still be wise to leave the ischæmic organ behind and to counter the threat of infection by conservative means, endocrine function is apparently preserved in some glands which have lost their power of spermatogenesis Bilateral torsion is not common (5-10% seems a reasonable estimate [30]), but, especially where one organ has already been lost, there is every reason to advise prophylactic fixation of the other

The British Pharmacopœia

THE publication of a new *British Pharmacopœia* is a matter of considerable moment in the medical world Even though the practising doctor obtains his information about pharmaceutical preparations from other—and less austere—literature, sooner or later his prescribing habits are affected by the crystallisation of therapeutic opinion which occurs every few years between the covers of the *B P* and the *Addendum* It is true that additions and deletions are so numerous that a *Pharmacopœia* might be regarded as a public declaration of a Commission's fallibility But the book represents objective opinion at the time of writing, and in these days remarkable developments are possible in the few years between official pronouncements

The influence of the *British Pharmacopœia* extends far beyond an implicit recommendation of the drugs listed For well-nigh a hundred years it has been a recognised book of standards It symbolises much that is of value in the British tradition its status has been

achieved through the disinterested service of a host of scientific workers who have looked for no reward beyond pride in a job well done. Admittedly, times have changed. The *B.P.* is no longer a catalogue of galenicals contributed by generations of empirical physicians. It is increasingly a compendium of pharmaceutical preparations included only after critical assessment by means of clinical trials, and the monographs and appendices create for the *B.P.* a unique position as a book of reference in laboratories as well as in the dispensary. This continuing revolution has been effected chiefly by the pharmaceutical industry—British and foreign. This point deserves emphasis. The new outlook in therapeutics has been made possible only by the vigorous application of scientific method and commercial enterprise. It is only fair to say also that the attitude of the pharmaceutical industry towards the Pharmacopœia Commission has been characterised by enlightened benevolence. All the leading firms have been quick to recognise the intrinsic worth of the *Pharmacopœia*, and they have encouraged their experts to help the Commission in every way possible. Further, they have regarded the inclusion of their products in the *B.P.* as a coveted token of official recognition of the therapeutic value of these preparations.

In this context, the *B.P.* 1958[1] may mark the end of an epoch. Among the "principal changes" to which reference is made in the introduction is the following statement regarding the use of colour:

> "Permission has been given in a limited number of monographs on tablets for the addition of a suitable colouring agent to the coating because unfortunately uncoloured tablets have not been made available. Similar provision has been made for some capsules."

The use of colouring matter in official preparations—except where there is a clear pharmaceutical justification—has been consistently forbidden by previous Commissions. The medical practitioner may be unlikely to regard this veto as of much importance if manufacturers prefer gaudy pharmaceuticals they are only falling into line with the confectionery trade and the motor-car industry. Nevertheless doctors must be increasingly aware that the polychromasia of the chemist's shop has introduced new hazards. The reference to a "principal change" is ominous, for clearly the commissioners were obliged to make a choice between principle and expediency. The manufacturers say in effect:

> "Here is a new drug synthesised and owned by our firm. It has been shown by rigorous clinical trials and by wide experience to be therapeutically valuable. You—the Pharmacopœia Commission—can hardly avoid including it in the next *B.P.* or *Addendum*. Now we, as the sole manufacturers, have decided to release this drug only in the form of a tablet with a coating artificially coloured blue. If therefore you include the drug itself in the *B.P.* you must accept our directions about the colour of the official tablet. If you publish in the *B.P.* a monograph describing the drug itself (a white powder) you will only make yourselves look ridiculous because we shall refuse to supply the preparation in any form other than that of the blue tablet. We know that when we first marketed this drug as a coloured preparation we did not follow the recommendations of the Commission, but we believe that by means of colour we can build up a conditioned reflex in the minds of patients and doctors whereby our tablet is favoured in prescribing for patients suffering from a common disease. This association of ideas is immensely important in the commercial world, so it must be allowed."

Though the permission now given to different manufacturers to market the same *B.P.* preparation in different colours may appear a small matter, it is quite a serious one if it means that the control of standards is no longer firmly in the hands of the commissioners. Someday a manufacturer may tell the Commission that there are so many coloured tablets that he has decided to introduce his new spasmolytic in the form of a crescent-shaped tablet because he has a special interest in the Oriental market. *B.P.* preparations of a new cardiac glycoside might be presented in heart-shaped tablets, and for a new diuretic preparation they might be reniform. These suggestions are by no means fanciful, for a manufacturer could justify his action by the kind of arguments used in favour of allowing colour.

We certainly do not suggest that standards and practices which differ from those of the *B.P.* are necessarily inferior. Further, there can be no quarrel with a manufacturer who deliberately disregards the rulings of the Commission and decides to go his own way. But having done so, he has no claim, we think, to ratification of his decisions by those whose standards are unrelated to commerce. The contribution of creative commercial enterprise to present-day medicine is very great, but its importance would not justify any weakening of the detachment with which the Pharmacopœia Commission have performed their different kind of public service. The printing of the Royal arms on their volume is evidence of their particular responsibilities as well as of their necessary privileges.

Support for the Family

TRADITIONALLY the good family has always looked after its weaker members—the old, the young, and the sick. The burden, even when willingly accepted, has often fallen unevenly, and in this century of small families, an ageing population, and working women, the system has shown signs of strain. Fortunately people have come to recognise that the larger society of the community, as well as the closer society of the family, has some responsibility for all its members, and the benefits of the Welfare State are the community's recognition of this duty. But the proper balance of responsibility between the family and the community is not easily reached. Over-protection can be a threat to the integrity and independence of the family. Indifference and lack of support may in the long run discourage even the most devoted relatives.

Some of the benefits which the State offers are dependent on a medical certificate, and because of this proviso and his knowledge of family circumstances the family doctor is well placed to judge how the scheme is working. Dr ASHWORTH in his survey of certification in a Manchester practice (p. 732) gives on the whole a good report, but he admits that a few of his patients' claims for sickness benefit were prolonged on social rather than medical grounds For instance return to work was sometimes delayed not by the worker's own illness but by the illness of other members of the family Concessions to domestic difficulties of this kind can be economical as well as humane, for the alternative is often a hospital bed, a home help, or a home nurse, any of which will probably cost the community more than an extra week or two of sickness benefit But if the need is real—and Dr Ashworth's examples suggest that it is—would it not be better to admit its existence and allow the doctor to authorise an official benefit to meet a family emergency? If, on a medical certificate, a healthy worker could claim an "emergency" benefit for a limited period of two or three weeks, to cope with a family crisis, the doctor need no longer uneasily feel that he is interpreting the rules of National Insurance rather freely The main difficulty, perhaps, would be the attitude of the employer, and of fellow workers, to this form of absenteeism Though in times of full employment many employers may allow their workers leave of absence under domestic duress, only a few of them, such as the London County Council, recognise it explicitly The majority view may be that industry cannot afford to encourage workers to leave their productive work, and admittedly the cost to the community through the loss of working time might well be heavier than the sums paid in actual benefit Even so, there might be a clear economic advantage through relief to the hospital and social services In the specially acute emergencies where a household is temporarily disrupted by the illness of the mother, an "emergency" benefit would make it easier for a husband, or a daughter, to take over the mother's duties temporarily, and, in days when help is hard to find outside the family circle, it might in fact be more useful than a benefit for the housewife in her own right, such as she has in Sweden

---

[1] British Pharmacopœia 1958. London: Pharmaceutical Press for the General Medical Council. Pp 1012. £3 3s.

Besides emergencies, there are lasting disasters when some member of the family must give up work entirely so as to enable an invalid to remain at home Severely disabled war pensioners can already claim an attendant's allowance, but the middle-aged daughter who gives up her job to look after her mother who has had a stroke is forced to seek National Assistance In theory there is of course no reason why she should not, but in practice an official benefit would be a helpful recognition of her work and a token of the community's support and backing Indeed from time to time it has been suggested that a modest allowance should be offered to relatives who undertake the care of bedridden old people, and this proposal has lately been put forward again by Mr Peter Townsend [1] as a result of his survey of old age in Bethnal Green To say that a benefit of this kind would destroy the solidarity of the family is one way of looking at it Another is that it would be a supplement which the community would offer the family to enable them to keep the old person at home An allowance of this kind, backed by the assurance of a regular visit from a home nurse or a home help, and regular breaks when the old person could stay in a hospital (as in the scheme described by De Largy [2]), might go a long way towards solving the problem of our old people Admittedly the frailty of old age is not the only cause of a possible breadwinner being tied to an impoverished home other equally deserving people, such as widows or deserted wives with young children, have to turn to the National Assistance Board for help. But old people have the administrative advantage of forming a large and fairly compact group Undoubtedly also the provision of hostels and hospitals stimulates the demand for residential accommodation, and any alternative method of looking after our old people which would break this expensive and often second-best circle is worth considering

Another family question, more complex and more prickly, is also set by one of Dr Ashworth's cases In one family the father prolonged his sickleave to look after two children who were ill, because the mother would have lost her job had she stayed at home This arrangement may well have been the best to meet the emergency of illness But in this family in normal times the two parents were apparently in full-time employment No-one has anything but sympathy and respect for the singlehanded parent who is forced to earn a living for a family and run the home at the same time, but where there are two parents—at any rate while the children are young—a stable family background is usually best provided by a whole-time mother There are few hard facts about the extent of "mother employment" Custom probably varies from locality to locality, and circumstances from family to family An ablebodied grandmother, for instance, may be acting as a competent and loving locum tenens But the uneasy feelings of many who work among children, especially in industrial areas, were lately expressed by the Bishop of Woolwich in his Mothering Day sermon [3] He pointed out that half the women in industry today are married So large a proportion probably includes too many mothers, and he asked "How can there be a home life when children come home from school to an empty house when mother is too tired at the end of the day for either children or husband?" His plea has been reinforced by a Lancashire vicar [4] who estimates that 5% of the children in one of his church schools return to homes where no parent and often no adult awaits them In our own columns [5] a psychologist has expressed his reluctant acquiescence in the provision of day nurseries because the mothers need the money and the local industries the labour To offer a mother money to stay at home to look after her own children may seem extravagant, and probably only a fairly substantial subsidy would be effective The French system of offering mothers a *salaire unique* related to the minimum wage and the number of children is admittedly expensive, but, if we count the cost in insecure and unsupervised children, our own laissez-faire system may not prove cheap

Annotations

POSTOPERATIVE METABOLIC CHANGES

The metabolic effects of injury have not yet been fully defined Starvation is widely believed to play only a small part in bringing about the increased urinary excretion of nitrogen and potassium and the reduced output of sodium, injury is supposed to be the most important single factor in producing these changes But Dr Abbott and his colleagues, whose report we publish this week, believe that operative trauma and anæsthesia are only minor factors and that dietary restriction, complications, previous nutritional state, and age are the major factors

They describe observations on the effects of cholecystectomy in 11 women and 2 men who were placed on one of three types of dietary regimen for three days before and three days after operation, the two periods of observation were divided by an intermission of three to four days during which an ordinary full diet was consumed

When 5% glucose solution alone was given for three days operation had little effect on the excretory pattern of sodium, potassium, or nitrogen When sodium and potassium were administered in addition to glucose the postoperative variations were similar to those who received glucose only, except in one patient whose wound became infected In a third group of patients 5% protein hydrolysate and 10% fructose were added to the glucose, sodium, and potassium Although these patients produced larger volumes of urine than those in the other two groups their losses of sodium, potassium, and nitrogen and of body-weight were smaller Nevertheless the protein and carbohydrate supplied were evidently not wholly adequate, because even in the control period there was a nitrogen deficit and some weight-loss

That so little metabolic disturbance follows uncomplicated cholecystectomy is not very surprising and raises the question whether this operation causes sufficient damage to provide an adequate stimulus—adequate, that is to say, for present methods of measurement and detection of the items of postoperative metabolic variation This doubt is strengthened by the distinct effect of a pyrexial complication in one patient of the series, and by the authors' statement that a larger metabolic disturbance is associated with severe blood-loss, necrosis, or injection There is abundant evidence that after injury urinary nitrogen excretion is closely related to the previous state of protein nutrition and the plane of protein metabolism, and that in malnourished patients nitrogen excretion may increase little, if at all, even after very severe operations In well-nourished patients, however, provided the surgical injury is sufficiently severe nitrogen output usually increases notably Since in simple starvation the urinary nitrogen output usually declines and seldom increases, the large increase of nitrogen output which follows many major operations can hardly be attributed to inadequate diet

The report by Abbott et al raises again the important question of what part intravenous therapy should play in postoperative treatment The metabolic disturbances recorded here do not appear to demand intravenous therapy, which is expensive and not entirely free of the risk of complications, such as chemical thrombophlebitis The argument for such treatment would be stronger if there were larger differences between control and postoperative periods, and between the group who received glucose, potassium, sodium, fructose, and protein hydrolysate and the patients who received only glucose Until much more is known about the metabolism and excretion of adrenal cortical hormones and their end-products little is to be gained by discussing the apparent conflict between the observations of Abbott et al and of Moore et al [1] and Steenburg et al [2] on the relation of nitrogen balance to urinary hydroxycorticoid excretion The postoperative metabolic disturbances are likely to be due, not solely to "permissive" adrenal-steroid activity or to local tissue damage, but rather to a combination of both processes, and local damage is likely to prove the primary stimulus

LABORATORY SERVICES IN SCOTLAND

Laboratory services in Scotland have developed somewhat differently from those in England Clinical pathology as practised in England is a recent development in Scotland, where in the past laboratory investigations on patients were carried out mainly by university departments of pathology (which really meant morbid anatomy), bacteriology, and biochemistry, and in many hospitals hæmatology is still a province of medicine rather than of pathology Even now, a very large amount of the clinical-pathological work in Scotland is done by the university departments of pathology, and probably a larger proportion is done "postally" than in England, this is largely inevitable because of the sparseness of the population in many areas, but possibly there is still too much centralisation in the university laboratories Another difference is that there is no separate Public Health Laboratory Service, and public-health-laboratory work is carried out by the laboratories that are also responsible for the hospital laboratory work

A committee was set up by the Scottish Health Services Council in 1956 to consider the future of the laboratory service In its report [3] this committee recommends that regional plans should be developed for the hospital pathological work, so that university departments should do only such routine work as is necessary for teaching and research As regards administration of the laboratory services the committee, while admitting that a case could be made out for a regional pathological service centrally administered by the regional boards, felt that the existing service under the boards of management should be continued, but with the important difference that there should be more centralised planning of laboratory services by the regional boards with the advice of a strong pathological advisory committee, which would include members of the regional board, general practitioners, medical officers of health, and other consultants, in addition to pathologists

The committee insists that boards of management must be prepared to take account of matters beyond the local interest of their particular hospitals and proposes that the laboratories under more than one board of management be grouped to provide a more comprehensive service Although the expenditure on laboratories has increased proportionally nearly twice as much as expenditure in the hospitals generally, much still remains to be done, and the committee proposes that special revenue and capital allocations should be made to the regional boards for laboratory purposes and that regional boards should not have the power to divert these allocations to other purposes

Much of the report is of interest to hospitals in England and Wales In particular 'a wider grouping of hospitals than by hospital management committee areas to provide comprehensive specialist pathology services is very desirable many hospital management committees have tended to try to build up a self-contained laboratory service, even though special facilities can more economically and advantageously be provided by grouping with hospitals in neighbouring groups The direct allocation of funds specifically for laboratory development is also worth considering

[2] Steenburg, R W, Lennihan, R, Moore, F D *ibid* 1956, 143, 180

[3] Department of Health for Scotland Scottish Health Services Council The Organisation of Laboratory Services H M Stationery Office 1958 1*s*

The committee maintains that there is no case for a separate public-health service, as in England, and suggests that the future of the two existing public-health laboratories should be considered with a view to their full integration in the main laboratory service Many may feel that in England the separation of the Public Health Laboratory Service from the hospital laboratory service is in places too wide, and that much might be gained by unifying the service at the periphery

THE HAMMAN-RICH SYNDROME

UNDER the heading " acute diffuse fibrosis of the lungs " Hamman and Rich [1] described in 1944 a peculiar disease of the lungs, of which altogether 63 cases have now been reported [2] Since most cases have a subchronic or chronic course the adjective " acute " has been omitted in later reports, and the disorder is now referred to as the " Hamman-Rich syndrome " or " diffuse progressive interstitial fibrosis of the lungs "

The disease affects adults of all ages, only 2 cases in children have been reported [3,4] The youngest patient ($2^1/_2$ years) was that of Baar and Braid,[4] the oldest (72 years) that of Peabody et al [5] The onset is usually insidious The presenting symptom is progressive shortness of breath, which becomes associated with cyanosis Cough may be present from the onset, profuse mucopurulent, occasionally bloodstained, sputum is a comparatively late symptom Finger-clubbing was noted in about a third of all cases Cor pulmonale and right-sided heart-failure develop in the late stages Radiographic examination shows in only about a third of all cases the appearance of diffuse reticular striation of lung-fields, and occasionally this is associated with minute cystic spaces or fine honeycombing In the other two-thirds of cases there may be slight changes, such as mottled opacities in the hilar regions, or the appearance of congestion or of pneumonic consolidation may be found Histological examination shows diffuse changes in both lungs, although in different areas the lesions may be of different ages Everywhere the interstitial tissue, particularly the interalveolar septa, is broadened either by infiltration with monocytes, lymphocytes, and plasma cells or by fibroblastic proliferation with or without formation of collagen fibres The alveoli are usually lined by cuboid epithelium, they are either empty or contain a moderate number of alveolar macrophages Hyaline membranes may be present, but are seldom abundant Capillaries in the interalveolar septa may be obliterated [2]

Luchsinger et al [6] studied " cardiopulmonary " function in the Hamman-Rich syndrome They found restriction of the pulmonary capillary bed with resulting insufficient diffusion of oxygen The thickened interalveolar septa and the destruction of capillaries lead to reduced alveolar-capillary " contact-time " and so to what Austrian et al [7] named " alveolar-capillary block "

In differential diagnosis Baar and Braid [4] suggest that the following conditions be considered (1) chronic indurative pneumonia, (2) bilateral bronchiectasis, (3) atypical pneumonia, and (4) the so-called " rheumatic pneumonia " Such disorders as pulmonary hæmosiderosis, retrograde lymphatic spread of thymic carcinoma,[8] or syphilitic pneumonia are easily differentiated on clinical and morbid-anatomical evidence In several cases diagnosis was decided by means of lung biopsy This procedure seems to be justified, because some workers reported remissions or possibly arrest of the disease by treatment with cortical steroids or corticotrophin together with antibiotics [2,9,10] Others,[4] however, have observed no benefit with this therapy

The ætiology of the Hamman-Rich syndrome is unknown It may be significant that some patients have signs of hypersensitivity, and that a few show, in addition to diffuse interstitial fibrosis of the lungs, changes characteristic of " collagen disease ", such as " wire looping " of renal glomeruli, L E cells, and periarteritis nodosa Possibly allergy is at the root of the disorder There are some indications that, although the Hamman-Rich syndrome is a clinicopathological entity, it does not always arise from the same cause Thus the case of Callahan et al [11] was probably a pneumocystis pneumonia while the case of an infant described by Donohue,[12] which was probably an example of the Hamman-Rich syndrome in an early stage, presented the histological changes of interstitial plasma-cell pneumonia without pneumocystis

THE RUSSIAN VACCINE

ANSWERING questions about the Russian vaccine which has been used in the treatment of multiple sclerosis, the Minister of Health said in the House of Commons on Feb 24 that the evidence at present available was not sufficient to enable an opinion to be given on the efficiency or safety of this vaccine He added, however, that he was prepared to advise the release by Customs and Excise of small quantities imported for individual treatment on the advice of the patient's doctor His department would continue to gather all the information they could

There is indeed little published evidence at present The story began in 1946 with the claim by Margoulis et al [13] that they had isolated a virus which was neutralised by the sera of patients with multiple sclerosis, and subsequently Margoulis and Choubladze evolved a vaccine for the treatment of multiple sclerosis It was a suspension of brain tissue of white rats or mice infected experimentally with a virus of acute encephalomyelitis of man The virus was inactivated by formalin Last year Dick and his colleagues [14] in Belfast examined the properties of the virus concerned—the SV strain of E H A virus Their results suggested that it was rabies virus They were unable to demonstrate any specific neutralisation of this strain with sera from patients with multiple sclerosis, and they pointed out that the reported improvement of 30% of patients who had had the vaccine[15] was no more than might have been expected from the spontaneous remission of fresh lesions in untreated patients

If the vaccine does in fact contain inactivated rabies virus, the Minister will be very reluctant to allow larger quantities to enter the country until the matter of its safety has been more closely examined The efficiency of the inactivation process must be assessed, and the risks involved in injecting brain tissue must also be weighed On the other hand, the interest which the vaccine has aroused springs largely from the sense of hopelessness which now surrounds the treatment of multiple sclerosis, and quite apart from the risk of concluding prematurely that the vaccine has nothing to offer, it is important to make plain to patients and their relatives in this country that every new idea is being carefully considered, even though the prospect is discouraging To make the course of justice more apparen in the case of this much-publicised vaccine the Minister might authorise the importation of a quantity for safety testing If the tests are satisfactory, clinical trials might then be arranged

MASSIVE VENOUS OCCLUSION

THE usual forms of thrombophlebitis are easily recognised, but the dramatic and often fatal blue phlebitis,[16] phlegmasia cerulea dolens, or massive venous occlusion,[17] is often confused with acute arterial obstruction The pathology of this form of phlebitis is not well understood, some cases are described in which the disease affected healthy people going about their usual routine, although in most instances it has complicated some other lesion The extensive venous thrombosis in this condition may plug the outflow by the major veins draining the leg, or by extending peripherally to the smallest radicles obstruct capillary blood-flow, a large volume of blood is thus dammed back and lost to the circulation, the oligæmia causes death in some 25% of patients, and gangrene develops in 50%[18] Edwards[19] has confirmed that the pressure in patent peripheral veins is extremely high, whether this high venous pressure is due partly to venospasm or whether there is associated arteriospasm is still disputed

Massive venous occlusion can be readily diagnosed when episodic attacks of thrombophlebitis have culminated in painful œdema of the limb, which is dusky The diagnosis is less easy when the disorder develops abruptly in a previously normal limb, but the severe pain, massive œdema, and turgid veins contrast sharply with the findings in arterial obstruction Treatment is by no means satisfactory Undoubtedly oligæmic shock must be rapidly corrected by transfusion, but the measures to be directed to the limb are less certain Those who believe that spasm is a factor in the persistence of the condition have advocated paravertebral block or spinal anæsthesia Edwards[19] was impressed by the improvement following spinal anæsthesia in 3 of his patients, although his continuous recording of venous pressure in the affected limb does not show convincing evidence of release of venospasm, whereas removal of an 8 in clot from the common femoral vein was followed by a considerable fall of pressure Thrombectomy has been carried out by others[20][21] and seems to be well worth while when it is feasible Veal[17] advocated a regime of passive exercise in the acute phase, with the purpose of pumping blood out of the limb, but this resulted in pulmonary embolism in one of Edwards'[19] patients

The value of anticoagulants is also disputed At the onset of the condition petechial hæmorrhages due to capillary hypertension may be present in the affected skin, and to increase clotting-time seems likely to worsen this bleeding tendency On the other hand, when thrombectomy has been performed or collateral channels have opened up, anticoagulant therapy may be desirable to reduce the liability to further intravascular clotting Even so, when by usual standards adequate anticoagulant therapy has been given, massive venous thrombosis has developed[19][22]

Though so little is known about the pathology of this disorder, and its treatment is far from satisfactory, early diagnosis can save life and minimise postphlebitic symptoms

SIR GORDON GORDON-TAYLOR

IN 1903 the University of London instituted the B SC. degree in anatomy The only candidates were two young men, Gordon Gordon-Taylor and Victor Bonney Being busy they decided to work through the night three times a week, sustaining themselves through the long hours by means of coffee essence heated over a Bunsen burner Both achieved first-class honours This story is told in the *British Journal of Surgery* for April, 1949, an issue dedicated to Sir Gordon, and last month, in honour of his 80th birthday, that journal once more honoured him by publishing a special Gordon-Taylor birthday number An introduction by Sir Cecil Wakeley, giving a brief account of his work, is followed by twenty-five articles on surgical topics by his associates and pupils The frontispiece is a reproduction of a portrait of Sir Gordon by Miss Anna Zinkeisen, which was presented to him at the Middlesex Hospital on March 27

The singleness of mind shown in his early anatomical studies has remained with him, and he has continued to work, write, and lecture Sir Cecil refers to his article on surgery of the innominate artery which dealt with work in progress when he was 72 Other topics on which he has written much and with great authority include hindquarter amputation, carcinoma of the œsophagus, and war wounds of the abdomen—he was consulting surgeon to the Fourth Army in the first world war and consultant to the Royal Navy in the second He has been a fellow of the Royal College of Surgeons for fifty-one years, he has been a vice-president, and has been vice-dean of the Institute of Basic Medical Sciences since its formation Surgery has been his life, though he was a classical scholar at Aberdeen before he began medicine, and he retains his love of Horace and is out of sympathy with some more modern, and perhaps more transient, entertainments He has done much to encourage young surgeons, and these and many others will join Sir Cecil Wakeley in his expression of esteem and good wishes to "the doyen of British surgeons"

DR CHARLES HARRIS has been elected vice-chancellor of the University of London for 1958-59

ABSENCE FROM WORK ON A MEDICAL CERTIFICATE

The Cost to Sickness Funds as seen from a General Practice

HENRY WILKINSON ASHWORTH
M B, B Sc Manc
GENERAL PRACTITIONER,
UNIVERSITY OF MANCHESTER EXPERIMENTAL HEALTH SERVICE

THOUGH I regard it as my duty to see that my patient has all the treatment he needs, I also feel some responsibility for seeing that he returns to work as soon as possible and does not draw unjustly on the insurance funds to which we all contribute The family doctor is well placed to assess the true extent of unnecessary absence from work, and, as it is often said that this abuse of the welfare service is widely practised, I decided to analyse the information offered by my practice for the year May, 1955 to May, 1956

Facts and Figures

The practice has 3300 patients and is part of the Darbishire House Health Centre, established by the University of Manchester as an experimental teaching health centre The age and sex distribution of patients is similar to that in the country as a whole The average number of items of service per year given to each patient was 4

Because I practise in a health centre and in almost ideal conditions, my sickness certification is probably stricter than that of some practitioners, though I still have the usual types of excessively demanding patients

Unjustified Claims

In my practice, as in any other, there are the obvious malingerers, and in this investigation I counted 10 I refused sick notes to all these patients

Next came a group of 44 women and 54 men to whom I did issue sick notes although I felt they were extending their absenteeism beyond the time strictly necessary on medical grounds These women made 53 claims and lost 634 days' work unnecessarily, for which they drew £176 in benefit, the men made 61 claims and lost 640 days for which they drew £234 Of the 44 women 18 were in the fifty-one to sixty-five age-group

These women are an independent group They are mostly going out to work to earn money to buy the extras in life, and they seem to change their jobs often They soon seem to disagree with their employer or frankly have long periods resting, which go beyond what I consider reasonable Now, if a woman complains of feeling tired, I will always issue her with a sick certificate for a week or two, but if, after that time, she still shows no symptoms or signs of disease, then I regard her as probably unjustified in prolonging her claim

Among the men the age-distribution was fairly even Again, these men all had bad absence records

Justified Claims

In the same period 114 women and 209 men in my view claimed benefit honestly and did not absent themselves from work unjustly on medical grounds

These people had periods of sickness which were likely to be of limited duration and the list does not include those thought to have some disability which will permanently interfere with their return to work The women made 135 claims, and lost 3143 days, for which they drew £863 in benefit, the men made 270 claims, lost 6561 days, and drew £2505

TABLE I

—	No of patients	Women			Men			
		No of claims	Days lost	Cost (£)	No of patients	No of claims	Days lost	Cost (£)
Unjust claims	44	53	634	176	54	61	640	234
Just claims	114	135	3143	863	209	270	6561	2505
Chronic unemployable sick	15	15	4368	1265	17	17	5544	2450
Deaths	1	1	246	82	3	3	618	303
Total	174	204	8391	2386	283	351	13,363	5492

The Chronic Sick

This is a group of 15 women and 17 men who, as far as can be seen, are not likely to resume work again The group is not static, because from time to time patients do return to work, even after years away from it, but the list does not vary much The women lost 4368 days and drew £1265 in benefit, the men lost 5544 days and drew £2450 in benefit

Deaths

During the year under review, 1 woman and 3 men died, and they had drawn some sickness benefit

The Composite Picture

If we set these figures against the background of my whole practice we get a true appreciation of their significance In all, 457 men and women made 555 claims and drew £7878 in benefit Of these, 114 women made 135 just claims and drew £863, and 209 men made 270 just claims and drew £2505, in short-term claims of limited duration (table I) The justified sickness claims for men and women came to £3368 About half the sickness claims are for limited periods, and half the money paid out in sick benefit goes to a very small group of chronic unemployable sick patients

In my view 98 patients made 114 unjust claims which cost £410 Thus, out of every five people who made a claim, one made a claim which was unnecessary or unduly prolonged Of 21,754 days lost, 1274 were lost unnecessarily (table II)

TABLE II

Total no of patients claiming benefit	457	No of patients making unjustified claims	98
Total no of claims made	555	No of unjust claims made	114
Total days lost	21,754	No of unnecessary days lost	1274
Total cost in benefit drawn	£7878	Benefit drawn unjustly	£410

These are the tables which a businessman might draw up in introducing an insurance scheme into his own works But they take little notice of the social and domestic conditions of the patients After all, it may well be that some of these patients, especially the women, have home commitments which necessitate their absence from work, and it may even pay the community to allow them temporarily to be away from work and to pay them insurance while they are off work

Social and domestic circumstances sometimes provide extenuating circumstances which allow me to accept claims even though there are insufficient medical causes These domestic factors may not be sufficient to warrant the patient going to the National Assistance Board and there is often an interweaving of the functions of the doctor and the National Assistance officer

For example, a man stays off work to look after two sick children during Whitweek The wife says that if she stays off work she will be dismissed Obviously it is in the interests of all that I should cover this man with a sickness certificate It is the most expeditious way of dealing with the situation Again, an epileptic gets drunk on a Saturday night. He wets the bed in his lodgings and gets expelled from the house as a result. He gets aggressive and will not go to work until he finds fresh accommodation, and he wants to fight his employer anyway What else can I do but accede to his request for a sickness certificate?

I therefore looked at these claims again, this time with the eye of a humane family doctor to see how many cases had mitigating circumstances Apart from the chronic sick and the dying, I estimated that out of 158 women, 14 had periods of sick-leave justified on social or domestic grounds Similarly, 11 men had mitigating circumstances The amount of benefit these patients had claimed was £144

Discussion

Whenever I have discussed unjustified absenteeism with my colleagues, I have met with reticence Many pretend that it does not exist, since to admit it implies that certificates which the practitioner issues are not accurate. Some ask me "Who is to say that a patient is fit if he himself says he is unfit?"

Patients who say they are not well enough to work and yet the doctor feels they are, usually fall into the following group

Those who are blatantly trying to draw sick-pay under false pretences

Those who insist they are not well enough for work and yet are working at home for friends or relations

Those who are completing their fortnight on the sick-list so that they can claim their three waiting days

Those who are changing their jobs

Those who are extending a holiday—e g, Whitsuntide or Easter

Those with very mild symptoms

This last group cause the greatest doubts in my mind, but knowing my patients, and often seeing them in the street, or cinema, or public house, I can form a shrewd assessment of the strength of their claims

Extenuating factors operate more often in the women's claims, since women have so many responsibilities in the home to their children or to invalids Indeed, after reviewing the social background of some of the women claimants, one appreciates more than ever the tremendous load which some of them carry The wonder is that more do not have to give up their work. But the Government have repeatedly made it clear that the general practitioner is responsible for deciding whether or not a patient is fit for work, and I, for my part, have no difficulty in accepting the role of arbiter in these cases

About 1 in 5 claimants make claims which are unjustified, but in money they draw only £410 between them As the whole sickness claims over the year amount to £7878 we may conclude that only about 5% of the money paid in benefits is unjustly drawn. When account is taken of social circumstances this figure may be reduced to about 3% This low percentage is largely due to the very great drain on the sickness funds made by the chronic unemployable patients

Until I began this investigation I was not aware how big a drain these patients represent. Numbering only 32 (15 women and 17 men), those in my practice draw almost £3700 in a year, or as much as all the short-term absentees put together

These people have to come to terms with their diseases Their happiness in life depends on how they do this but many men fight on in a battle which gradually wears them down. They are often loth to surrender their jobs Sometimes it is possible to get a man to take over the household duties whilst the wife becomes the breadwinner, but most men regard this as an affront to their dignity Women seem to settle down more easily when once they have realised the chronicity of their complaint.

Doctors themselves become apathetic in their treatment. It is hard to generate enthusiasm in dealing with a patient who has attended regularly for years, and one colleague has suggested that any patient who is on the sick-list for more than a year should change his doctor Certainly the doctor needs to ask himself whether everything possible is being done for his chronic sick patients, not only in treatment but in the equally important realm of human relationships and social work.

The disablement resettlement officer has a part to play in trying to place these patients in work, but a closer link needs forging between this officer and the general practitioner The chronic-sick patient often becomes sullen and suspicious, believing that people think he is malingering But hope for the future lies rather in preventing patients from reaching this condition rather than in trying to rehabilitate them when they have got there Considering the cost of these patients in sickness benefit, the community would be justified in spending large sums if necessary in preventing incapacity

In these days of full employment we are employing people who once would not have been considered on the labour market and we must expect a higher sickness-rate than hitherto In global figures, in 1954-55 about £840 million was paid in sickness benefit My findings suggest that 3%, or £2½ million, was claimed unjustly This does not seem to warrant any radical change in our certification procedure On the contrary, it demonstrates how small a proportion of working people draw benefit wrongfully, and how well the people in this country play their part in the new social order

DOCTORS' PENSIONS

NEARLY every doctor in the National Health Service pays superannuation contributions After 10 years' service, if he is over 60, he becomes eligible for a pension, and with the approach of the tenth anniversary of the start of the N.H S, many of the more senior doctors will wonder where they stand The scheme is governed by regulations[1], two booklets explain the regulations concisely—one as they affect family doctors[2] and the other, more tersely, as they affect all N.H S employees[3]

The conditions on which a pension is paid are the same for specialists and family doctors, though the method of calculation may be different A pension and a lump sum (the retiring allowance, which has nothing to do with the compensation paid on retirement for loss of the sale of a practice) are payable after 10 or more years' service to a doctor aged 60—at an earlier age only if he is permanently incapacitated The normal "pensionable age" (i e, the age at which contributions cease and service is no longer reckonable in calculating benefit) is 65, a family doctor aged 60-64 may apply to the Minister to have his pensionable age extended to any up to 70 (The fact that the doctor has reached pensionable age does not mean that he can no longer practise) Other benefits provided under the scheme include an injury allowance (for those permanently incapacitated by injury sustained or illness contracted in the course of duty), a short-service gratuity (for those with 5–10 years' service retiring through incapacity), a death gratuity, and a widow's pension

---

[1] National Health Service (Superannuation) Regulations, 1955 S.I 1955, no 1084 H.M Stationery Office 3s

[2] Barry H Superannuation for the General Medical Practitioner. London Heinemann Medical Books. 1955 Pp. 20. 2s. 6d.

[3] National Health Service Superannuation Scheme (England and Wales) an Explanation. H.M. Stationery Office. 1956. Pp 24. 1s.

The amount of benefit depends on length of service and amount of pay For a general practitioner the annual pension on retirement is 1½% of the total "superannuable remuneration" (see below) during the last 45 years of service, or the whole period of service if this is less than 45 years If he retires before 65 through incapacity, his pension is 1½% of his remuneration over not less than 20 years (unless he would have had less than 20 years' service at "pensionable age") The lump sum is 1½% of the total superannuable remuneration for married men and 4½% for others, if a man's wife has died or been judicially separated from him, the figure is 1½% for each year of service before the wife's death or separation and 4½% for each year after (The difference is because of the widow's pension liability) If a practitioner has completed 10 years of service, his widow is entitled to a pension, which is in general a third of the pension her husband might have expected, but if she is entitled in her own right to a pension in the same scheme, she is ineligible for a widow's pension (unless she is a practitioner, when she draws both pensions) A death gratuity is usually a year's remuneration or 1½% of the total remuneration, but benefits already paid are deducted from it

Full-time specialists (consultants and S H M O s), like other salaried staff, are entitled to a pension of $^{1}/_{80}$ (1¼%) of their "average remuneration" (i e, the average annual remuneration during the last three years of service) for each year of contributing service, to a maximum of $^{45}/_{80}$ The minimum pension for retirement through incapacity is usually $^{20}/_{80}$ of "average remuneration" The lump sum is $^{3}/_{80}$ of the "average remuneration" per year of service (up to 45), or $^{1}/_{80}$ for married men The death gratuity, widow's pension, and injury allowance are calculated on corresponding lines A part-time specialist has his benefits calculated in the same way as a practitioner's, unless he spends at least nine notional half-days a week as a specialist and has asked the Minister to direct that his benefits be calculated by the other method

For full-time specialists, "superannuable remuneration" means salary, for practitioners it means all payments by the executive council, less a deduction of the salary paid to any assistants, and of a sum representing practice expenses—50% of payments for mileage and pharmaceutical services, and 30% of most other payments In the case of a partnership, the remuneration is regarded as being divided equally among the partners unless they have elected otherwise

One or two examples follow

An unmarried family doctor who has served 10 years and in that time been paid £20,000 (£14,000 after deduction of practice expenses) will be entitled to a pension (1½%) of £210 p a and a lump sum of £630

A married family doctor with 10 years' service, who has been paid £35,000 (including £400 in mileage allowances) and has paid an assistant £10,000, will have a net remuneration of £17,360 His pension will be £260 8s, and he will receive the same sum as a retirement allowance If he dies, his wife will receive a pension of £86 16s (If this doctor had stayed in the service for another five years at the same rate of pay, these sums would all be 50% higher)

A full-time consultant, after 10 years in the hospital service and earning £3100 p a for the last 3 of them, would receive on retirement a pension of £387 10s

These figures are no more than a general guide, because there are many ways in which the position outlined above may be different in individual cases, thus service in the Armed Forces, employment of a trainee assistant, breaks in service, and the National Insurance scheme (those who opted for reduction of contributions on account of National Insurance will get a reduced pension) all affect the amount of pension payable A doctor who is uncertain about his own position can get information from the Secretary, Ministry of Health, Health Services Superannuation Division, Government Buildings, Honeypot Lane, Stanmore, Middlesex, or, in Scotland, from the Department of Health for Scotland, Health Services Superannuation Branch, Broomhouse Drive, Saughton, Edinburgh, 11

BRITISH PHARMACOPŒIA 1958

THE new edition of the *British Pharmacopœia*,[1] which will become official on Sept 1, includes 160 additions

New work on the clinical applications of antibiotics has led to the inclusion of tetracycline and oxytetracycline Phenoxymethyl penicillin and benzathine penicillin (tablets and also an injection) are added in recognition of the occasional justification of oral medication with penicillin

Experience of sensitivity reactions to local applications of penicillin doubtless accounts for the disappearance of penicillin ointments and cream from the official list Erythromycin becomes official Other antibiotics which are important but which have limited therapeutic uses are also included—bacitracin, neomycin sulphate, and polymyxin B sulphate The range of sulphonamides is increased by the addition of sulphamerazine and phthalylsulphathiazole Few will deplore the disappearance of sulphanilamide and sulphathiazole

Among the modifications of biological products is a new range of combined vaccines diphtheria and pertussis vaccine, diphtheria, tetanus, and pertussis vaccine, and typhoid paratyphoid A and B, and tetanus vaccine Human γ-globulin qualifies for official recognition as a safe and more effective alternative to convalescent serum in the prevention or attenuation of several infectious diseases of childhood

A considerable number of the new drugs listed are used principally in tropical medicine chloroquine, primaquine, and amodiaquine are antimalarials, chiniofon sodium is a well-established remedy for amoebiasis, dapsone and solapsone are of value in leprosy, lucanthone is used in schistosomiasis, and there are many others Hexylresorcinol, an anthelmintic in roundworm infestation, is reinstated Piperazine preparations, which have proved valuable in threadworm infestation, are also given a place

From the welter of anti-histamines those chosen by the Commission are antazoline, chlorcyclizine, diphenhydramine, and phenindamine Chlorpromazine is also included, though its antihistaminic action is relatively unimportant—compared with its uses as an anti-emetic, to enhance the effect of analgesic drugs, and in certain psychiatric disorders

Of the barbiturates, amylobarbitone, butobarbitone, and cyclobarbitone are added Barbitone and hexobarbitone go out It is odd that carbromal should have had to wait so long for official recognition as a relatively mild hypnotic Pentolinium (for arterial hypertension) becomes official just when it is losing ground in favour of mecamylamine—which may be expected to become official in the next *Addendum* The alkaloid reserpine, from the ancient drug rauwolfia, becomes official with a dose of 0 25–1 mg daily, but the need for conservative dosage—in order to minimise the risk of producing psychiatric disorders—may raise misgivings about the drug before the *B P 1963* is published

Endocrinology contributes the insulin zinc suspensions and preparations of hydrocortisone, prednisone, and prednisolone, and there is thyroxine sodium—a research tool rather than a necessary alternative to thyroid *B P* in clinical practice

---

[1] This is discussed in a leading article on p 726

Neurologists have evidently convinced the Pharmacopœia Commission of the value of benzhexol, ethopropazine, and procyclidine in the management of parkinsonism, that mephenesin is worth a place in the treatment of tetanus, and that troxidone and paramethadione have, on balance, earned official approval in petit mal Suxamethonium chloride is already widely used by anæsthetists as a short-acting relaxant of voluntary muscle

New official drugs notable for their actions on the alimentary canal are the adsorbents (in gels and tablets) and spasmolytics such as propantheline bromide, and the revival of atropine methonitrate (now official) provides not only the physician's alternative to the Rammstedt operation but also the pharmacologist's oblique commentary on the spate of new synthetic spasmolytics The inclusion of procainamide—used as an alternative to quinidine to prevent bursts of extrasystoles—and of noradrenaline acid tartrate is not surprising, but the replacement of amphetamine by dexamphetamine must have called for nice judgment

Among the drugs which are best left in the hands of highly specialised practitioners is the cytotoxic substance mustine, used in Hodgkin's disease Folic acid has necessarily achieved official status, but its very limited applications have also been realised

The *B P* is by no means merely a physician's manual The surgeon will find here a number of interesting items including absorbable dusting-powder, absorbable gelatin sponge, oxidised cellulose, dextran, hyaluronidase, and diagnostic agents

Upwards of 130 drugs or preparations have been omitted Clove, fennel, nutmeg, and quassia all take their leave—no doubt to the chagrin of older practitioners who will find no consolation in the offer of sodium radio-iodide (^{131}I) and sodium radio-phosphate (^{32}P)

Other deletions which are significant of the climate of opinion in pharmacology and therapeutics are arsenic trioxide and the organic arsenicals, the bismuth salts, mercurous chloride, tincture of digitalis, spirit of ether, and serum gonadotrophin

Symposia

ANTERIOR-PITUITARY GLAND

A study group met at the Ciba Foundation, London, on March 11, under the chairmanship of Prof H L **Sheehan** (Liverpool), to review developments in knowledge of the anterior-pituitary gland

Hormone Content

Dr A. R **Currie** (Glasgow) reviewed factors affecting the yield of hormones extracted from human pituitary glands obtained within four hours of death Both the age and the sex of the patient influenced the content of gonadotrophins and of prolactin In pituitary tissue of women in the reproductive period of life the gonadotrophin content was relatively low, while in glands obtained from women at or beyond the menopause the yield was some three or four times higher than that found in premenopausal patients Gonadotrophic activity was also shown in pituitaries obtained from men, the content of stored hormone appeared to rise with advancing years Prolactin activity could not be detected in the glands of young men or of women before the menopause, but in postmenopausal women and in men over 50 prolactin activity was present, the amount being greater in women than in men In the case of the posterior-pituitary hormones, assays were conducted for pressor, antidiuretic, and oxytocic activities In all the glands studied the pressor activity closely paralleled the antidiuretic activity, while the relation of the pressor to the oxytocic activity was very variable The yield of posterior-pituitary hormones did not seem to be affected by age or sex or by trauma or other forms of "stress" immediately before death

Acromegaly

Dr P M F **Bishop** and Dr J H **Briggs** (London) discussed the prognosis in about a hundred cases of acromegaly 80% of these patients had died before the age of 60, most from cardiovascular causes They concluded that the modern treatment of acromegaly was not sufficiently radical and that a higher proportion of patients should be treated earlier by surgical means

Dr R **Luft** (Stockholm) believed that hypophysectomy was most likely to be helpful in acromegalic patients who had concomitant hypertension and cardiovascular disease Methods of assessing the activity of the disease were also discussed Prof A **Querido** (Leiden) had found neither the estimation of serum-inorganic-phosphorus nor the urinary excretion of creatine to be of any value in this respect Dr P J **Randle** (Cambridge) pointed out that the plasma insulin-like activity, determined by the rat diaphragm test, was considerably higher in acromegaly than in health, and suggested that this estimation might be a useful index of activity

Corticotrophin in Rheumatoid Arthritis

Dr **Oswald Savage** (London) reviewed his experience with long-continued corticotrophin therapy in severe rheumatoid arthritis In cases where, with such treatment, 17-hydroxycorticosteroid excretion rose appreciably, a satisfactory remission was usual If, on the other hand, the corticotrophin therapy had little effect on corticosteroid output, the course of the disease was usually unaffected Dr Savage concluded that mild adrenal stimulation was of value in relieving the symptoms of severe rheumatoid arthritis, and was more satisfactory than oral steroids

Gonadotrophins

Dr A C **Crooke** (Birmingham) said that in work on urinary gonadotrophins two assay methods were used, one depending on ovarian enlargement in intact mice treated with human chorionic gonadotrophin ("augmentation test") and the other on the mouse uterus test The former method had been claimed to be specific for follicle-stimulating-hormone (FSH) activity, the latter was not specific for either FSH or interstitial-cell-stimulating hormone (ICSH) and probably provided a useful index of "total gonadotrophic activity"

He reported parallel assays by the two techniques in a woman during the normal menstrual cycle, and claimed that the ratio of urinary FSH to urinary ICSH varied at different stages of the cycle Dr Crooke also described a method for the extraction of gonadotrophins from urine, based on the use of benzoic acid and tungstic acid, and claimed that this gave better yields than those obtained by the kaolin method

Dr J A **Loraine** (Edinburgh) questioned the specificity of the augmentation test and pointed out the advantages of using a method, such as the hypophysectomised-rat-prostate test, which was generally assumed to be specific for I C S H activity He suggested that the most satisfactory procedure for extracting gonadotrophins from urine was the kaolin-acetone method with appropriate pH control, including, in the case of low-titre urines, the tricalcium phosphate step

Anterior-pituitary Failure

Professor QUERIDO recalled that the earliest signs of pituitary failure were generally those due to absence of gonadotrophin secretion, and described a young woman and a young man showing hypogonadism only He also described a family in which two brothers had symptoms attributable to thyrotrophin deficiency alone and in which several sibs were found to have abnormally low levels of protein-bound iodine in the blood

Prof P A BASTENIE (Brussels) described the use of a "coefficient of ^{32}P exchange" by red cells as a measure of the activity of thyroid hormone

Prof R S MACH (Geneva) noted that aldosterone secretion, determined by urinary assays, continued in patients with panhypopituitarism

Report from Mayo Clinic

Dr E H RYNEARSON (Mayo Clinic) discussed the endocrine complications in 153 patients subjected to operations on the pituitary He emphasised that permanent diabetes insipidus was an unusual sequel except where damage extended high on the stalk

His colleagues at the Mayo Foundation had prepared differential suspensions of isolated anterior-pituitary cells, he showed illustrations of single acidophil, basophil, and chromophobe cells prepared from rat pituitary tissue

Dr Rynearson reported 153 cases of Cushing's syndrome, 33 of which were due to adrenocortical tumour In the remainder the cause was adrenocortical hyperplasia, and in 12 of these radiological examination showed the presence of a pituitary tumour Of these 12, 7 were treated by total bilateral adrenalectomy and only in these patients was there evidence of progressive enlargement of the pituitary tumour after operation In each of 5 pituitary glands subsequently available for histological examination, the predominant cells were found to be chromophobe

Dr LUFT remarked that in 5 of his patients with Cushing's syndrome there was evidence of pituitary enlargement, all were subsequently shown to have chromophobe tumours of the pituitary

Pituitary Irradiation

Dr J H LAWRENCE (Berkeley, California) described the results of pituitary irradiation in 50 patients mostly with advanced breast cancer The apparatus, an 800 meV cyclotron, provided a stream of high-energy α particles The total dosage administered to the pituitary ranged from 14,000 to 30,000 rads, but at present 22,000 rads was given over a period of two to three weeks Pituitary function was assessed by urinary gonadotrophin and corticosteroid assays and by radio-iodine studies In most cases it was found that pituitary activity declined some two months or more after treatment, but no attempt had been made to correlate the pre-treatment hormone levels with the response to therapy No permanent nerve-damage was noted, though in some cases there were transitory visual-field defects

Growth Hormone

Dr LUFT, working in collaboration with Dr D IKKOS and Dr C A GEMZELL, had observed the metabolic effects of human growth hormone (10 mg a day) in a healthy subject, a patient with rheumatoid arthritis, and 3 juvenile diabetic patients who had previously been subjected to hypophysectomy for vascular complications[1] In the healthy subject and in the patient with rheumatoid arthritis the effects of growth hormone were almost identical, and included striking retention of nitrogen, as well as some retention of phosphorus, potassium, sodium, chloride, and calcium After periods of treatment of sixteen and twelve days respectively there was some rebound loss of nitrogen In 2 of the diabetic patients administration of growth hormone was associated with rapid deterioration in their condition, blood-glucose levels rose sharply and glycosuria and ketonuria were much increased In view of these complications therapy had to be discontinued after two days In the 3rd diabetic patient there was evidence that the hypophysectomy had been incomplete, in this patient the deterioration under treatment with growth hormone was not apparent until the seventh day

Prof RUSSELL FRASER (London) referred to the effects of a similar growth-hormone preparation which had been made available for clinical trial in the United Kingdom by Prof F G Young and his coworkers in Cambridge Over very short periods of therapy results similar to those reported by Dr Luft had been obtained

Medicine and the Law

Medical Evidence of Diminished Responsibility

A LABOURER, aged 52, was convicted at Durham Assizes of the capital murder of a 15-year-old boy At the trial the defence of diminished responsibility, under section 2 (1) of the Homicide Act 1957, was raised, and he appealed against his conviction on the ground that the verdict of the jury rejecting that defence was unreasonable and not supported by the evidence

On appeal, his counsel said that three doctors were called for the defence The evidence of a senior prison doctor was that the labourer was a sexual pervert lacking in moral responsibility, with a mental age of less than 10 years The doctor had formed the view that the labourer was feeble-minded and had a psychopathic personality, and those two factors together constituted an abnormality of mind which substantially impaired his responsibility for his acts A consultant psychiatrist had concurred in that opinion, and a third doctor had come to a similar conclusion There was no medical evidence to the contrary Counsel submitted that on that evidence no reasonable jury could have found other than that the labourer had been suffering from such an abnormality of mind as substantially impaired his mental responsibility for the crime he had committed

On behalf of the Crown it was submitted that abnormality of mind was a variable and not a constant condition and therefore the onus was on the defence to establish to the jury on the balance of probabilities that at the time of the crime and not at any other time there was an abnormality operating on the labourer's mind which substantially impaired his responsibility It was perfectly open to the jury at the end of the medical evidence to say that they were not so satisfied The labourer's case must rest on the ground that the verdict was unreasonable

---

[1] Preliminary communications by Dr Luft and his colleagues appear in this issue on pp 720 and 721

The basis of the medical evidence as to the abnormality of mind reducing mental responsibility was that it consisted of two ingredients—first, that the appellant was feebleminded and had the intellect of a boy of 10, and secondly, that he had a psychopathic personality As regards the latter, the medical evidence was that it was episodic and recurrent Taking into account the nature of the two ingredients constituting the abnormality and the whole of the circumstances of the case it was open to the jury to say that diminished responsibility had not been established To say that they must be bound by the medical evidence would amount to dispensing with a jury

The LORD CHIEF JUSTICE, after a short adjournment, said that the court would allow the appeal and substitute a verdict of manslaughter for the verdict of murder given at the Assizes The reasons would be given at a later date The sentence upon the appellant was that he would be imprisoned for 20 years

REGINA *v* MATHESON *Court of Criminal Appeal* Lord Goddard, *C J* Streatfeild, Donovan, Slade, and Havers, *J J* March 24, 1958 George Waller, Q C, and Peter Taylor (registrar, Court of Criminal Appeal), P Stanley-Price, Q C, and R Rawden-Smith (Director of Public Prosecutions)

Barrister-at-law

Diminished Responsibility Again

The new defence of diminished responsibility has been successfully pleaded in the case of Graham Harold Geer, a 17-year-old youth charged with the murder of his stepmother [1]

Counsel for the defence told the jury that they would have to consider three points before they could return the verdict he asked for They must feel sure that Geer was suffering from an abnormality of the mind at the time of the offence If that was the case, they must decide whether it was caused by a disease Thirdly, if it was abnormality of the mind causec by disease, did they think it substantially impaired his responsibility for the killing?

Dr F H Brisby, principal medical officer at Brixton prison, said that Geer had been under his care from March 1 to 6 He had found that Geer was suffering from schizophrenia at the time of the killing There was no doubt that the disease had impaired Geer's mind and had affected his responsibility for the killing

Dr T C N Gibbons, consultant psychiatrist at the Maudsley Hospital, appointed by the Home Office to examine the accused, said that he entirely agreed with Dr Brisby's diagnosis

The jury found Geer not guilty of murder but guilty of manslaughter in accordance with section 2 of the Homicide Act, 1957

The judge sentenced Geer to imprisonment for life, saying that he was concerned that there should be proper punishment and also provision for Geer's future "I feel it right that I should give you such a sentence as will enable it to be reviewed from time to time I hope some time, and not too long, it will justify those responsible for you to allow you out again "

Compulsory Blood-test Refused

A husband, who is petitioning for divorce on the ground of the wife's alleged adultery, asked the court for an order to compel the wife to submit herself and her child to a blood-test with a view to obtaining evidence of the child's paternity A Scottish judge refused to make such an order and his decision has been upheld by three appeal judges [2] In the words of one of the appeal judges, the proposed order would be "an invasion of private right which is not consistent with our present methods "

Lord Thomson said that the most plausible way in which the argument for the husband could be put was to say that, owing to a new medical technique, evidence might be made available which would assist the court in discovering the truth It was in the interest of justice that the truth should be discovered, this method was scientific and objective and it was just obscurantism on the part of a court to refuse to avail itself of it

His Lordship considered, however, that this way of putting the argument obscured and misrepresented the problems presented They were not asked to say anything about the value of such evidence What the husband was asking the court to do was to compel the opposite party to the action to bring forward evidence which under normal circumstances she would not be under any obligation to furnish Moreover, it was evidence which could bring little advantage to the defendant, whereas it might be used strongly against her

His Lordship also referred to the problem of enforcing such an order Enforcement would mean the compulsory infliction of a surgical operation—a minor one, no doubt, but nonetheless an invasion of the person of the wife—or, if the court were not prepared to go that length, it would have to regard her refusal as a contempt of court

As to the child, Lord Thomson said that it seemed to him impossible, on any view of the problem, to compel a third party to undergo an operation in order to provide evidence for a plaintiff or a defendant

Lung-cancer Damages Claim

A New Orleans woman is suing two American tobacco manufacturers for $700,000 on the ground that her husband died from lung cancer caused by smoking their cigarettes His vocal cords had been removed in October, 1954, because of cancer, and he died of lung cancer in July, 1955 The judge declared a mis-trial because some members of the jury had received telephone inquiries as to their smoking habits, the trial is unlikely to come up again before November [1]

The widow says that her husband died of lung cancer in 1955 after smoking two packets of cigarettes a day for forty years, and claims that the defendants were negligent in failing to give warning about the deleterious effects of their product The defence will, it is understood, be based on a charge of contributory negligence on the ground that the deceased did not exercise due care in his smoking habits

Public Health

Vital Statistics for 1957

IN his latest quarterly return [2] the Registrar General gives some provisional figures for England and Wales in 1957 The live-birth rate was 16 1 (highest since 1949) and the death-rate 11 5 per 1000 (0 2 less than in 1956) The infant-mortality rate was 23 0—0 7 lower than in 1956, the previous low record

In the last quarter of 1957 the influenza epidemic was manifest in the death-rates of 924 (450) per million from pneumonia and 496 (23) from influenza, the tuberculosis death-rate was 135 (112) (Previous year's figures in parentheses)

The population at June 30, 1957, is estimated at 45,043,000, it is expected to increase to 50,370,000 in 1997 The excess of females was 1,479,000 in 1957, this figure is expected to fall to 556,000 in 1997

In England Now

A Running Commentary by Peripatetic Correspondents

"SHAN'T be long," said my friend, "the meeting will be over in half an hour and then we can have a gossip with the chaps " I sat down on the hard bench My eyes slowly became accustomed to the gloom I became aware that I was not alone Not by any means, for there in a gigantic glass case along the wall, unlit and unlabelled, stood glowering, not one, nor even two, but a whole row, almost a platoon, of giant skeletons I was suitably impressed My first thought was that some past member of the staff had been a gorilla hunter in his spare time And what a hunter, what a bag! For the five largest skeletons, if I was not mistaken, were clearly members of the same family

But on closer inspection I began to waver There were no bullet marks anywhere and in the case were several pygmy apes which no self-respecting gorilla hunter would ever shoot, much less put in a glass case So my thoughts turned to anthropologists, who, after all, are only frustrated gorilla hunters Could this be one of those demonstrations illustrating the Descent of Man? But if so, at which end of the series did one start? True the gorillas were right for size and one had the blackened teeth of a confirmed smoker, but on the other hand the only skeletons with measurable brain pans were the pygmies with long tails—the gorillas were just solid bone from the neck up It was all very difficult Also where was the photograph that tradition demanded showing the anthropologist, capped and gowned, with one hand laid fondly on the skull of the missing link? Where were the labels and the book of words? Whoever heard of an inarticulate anthropologist?

Perhaps, I reflected, it's only a job lot of monkeys After all, why should I expect a medical school of all places to keep its skeletons in cupboards? The minutes ticked on, thirty, sixty, ninety Could it simply be that the traditional way of shaking off the unwelcome visitor was to arrange to meet him here and then quietly disappear, leaving the exhibit to do the rest? I looked again at those empty orbits My spine sagged But I had maligned my friend "Ah there you are," he said, turning up only an hour late "Come and see this old photo of Bayliss and Starling and Sydney Ringer, look at those handlebar moustaches, doesn't that one look like a billiard marker? What about this?" he said proudly, knocking over a cup of tea and pointing to the framed strips of toilet roll on which the impecunious but resourceful young W B Cannon had traced his first radiographs of the stomach. "And," he concluded pointedly, "do stop walking around as though you were going to touch the ground with your knuckles It wasn't my fault the meeting went on so long Kindly remember that you are in England now "

* * *

John said we hadn't a hope in the M R C P because of lack of clinical material We are psychiatric registrars and our stethoscopes were seldom out of our pockets

"We'll find our own clinical material," I said

"Where?"

"Here, in the psychiatric clinic "

It was hard work at first, but it taught us to do thorough examinations quickly Gradually we built up our clientèle Even John was impressed at the amount of underlying pathology we found in psychiatric patients Monday was the day for our cardiac clinic Patients with murmurs in their hearts attended regularly and physical check-ups were combined with their usual treatment Tuesday was reserved for neurology, Wednesday for metabolic diseases, and Thursday for obscure physical signs On Fridays we salved our consciences and saw patients in physical health

Our knowledge of clinical medicine increased rapidly Moreover, during those months we correctly diagnosed five carcinomas, one endocarditis, and a parathyroid tumour, all in need of urgent treatment But the interesting result of our new methods was the improvement in the psychiatric condition of our "special" patients Even some of the chronics improved so much that reluctantly we felt obliged to discharge them

Now that we are M R C P s these unusual psychiatric techniques have been modified We couldn't keep it up for ever, but we regard it as a successful experiment from all points of view

* * *

I've got flu, and for four days my temperature has been over 101 I can't lift my head from the pillow, but during that time I have mapped out in my mind a new investigation on the development of antibiotic resistance in the staphylococcus, the plot and a lot of detail for a novel which I know will be a best-seller, and two anecdotes for the peripat When my temperature gets down to normal I know the investigation won't get much further, the novel idea will be dustier than its projected jacket, and the peripatetic contribution will be one of the ones the editor files instead of publishing But when I look back, I have discovered that, if I have made any original contributions to anything, the three I like best were all conceived when in bed with a cold Is it the idleness, or is it the temperature? You know the perennial argument on creative energy and the tubercle bacillus With tuberculosis a dying disease, are we to rely on the influenza virus for our inspiration?

* * *

Entering the field of clinical psychology for the first time one is faced by a bewildering array of tests, subtests, and questionaries measuring every imaginable (and the odd unimaginable) human function Clerical speed, finger dexterity, manual dexterity, and symbolical manipulation, to mention but a few, yield their secrets to indices of significance, deviation, and standard error *One is happily the donor rather than the recipient*, but even so the use of the vocabulary test is a humiliating experience, especially where the patient casually guesses his way to the bottom of the column and one has to consult a dictionary to know if he is right Sadly one discovers that I Q s of over 120 depend on a knowledge of words one has never heard of, let alone understood A post-psychological depression sets in, but as the delusions of inferiority recede one asks oneself "Why?" Our test-key tells us that "minatory" means "threatening" and "traduce" means "misrepresent" O K , so why bother with the former words at all? And the same to putative, heuristic, and the lot of the 120-plus words Some complex technical words are needed, and we are used, of course, to *professorial perorations (sorry, speeches)* which include the occasional lexicographic peculiarity In general, though, I feel that words incomprehensible to more than I in 400 don't help I have therefore devised *a formula for* dealing with semantic extravaganzas of obscure comprehensibility I call it the commonsense test (my sense being remarkably common) If I can't follow an author without dragging along the *Oxford Dictionary* (2 vols), I consider it's a lot of rot

* * *

The R S O was a gentle person, and it was with diffidence that he knocked on the door The Hospital Board was in full session

"I came about the operating-table, sir "

"Yes "

"It is a wooden one We've had it forty years, and it has none of the things operating-tables ought to have After forty years, you know, it's getting rather—high "

"I think you came to us last year about it, too, Mr ——?"

"Yes, actually, I did "

"We remember We pointed out then, of course, that a new one is expensive—most expensive But we are sympathetic about your request We will give it every consideration "

"Thank you, sir "

"All right, Mr —— *Good afternoon to you* "

"Shall I come next year, sir?"

"By all means, my dear fellow By all means "

A little later, with equal diffidence, he knocked on the door again The meeting was still in full session

"I came about the operating-table again, sir "

"Have we not met already on the subject, Mr ——?"

"But we've had it forty years It's a *wooden* one "

"And we have heard this already, Mr —— "

"Yes, sir, but the situation is somewhat changed I have just been to the theatre, and I have chopped it up Good afternoon to you, sir "

Letters to the Editor

CONSULTANT DISTRIBUTION, WAITING-LISTS, AND UNDEREMPLOYED SENIOR REGISTRARS

SIR,—Many fully trained senior registrars remain inadequately occupied while the profession and the Ministry fail to respond to the needs of the community or the plight of the registrars. However, facts are gradually emerging to prove the inequity of consultant distribution which many of us have suspected for years.

Replies from the Minister of Health on Jan. 26, 1958, elicited this information:

Region	*Waiting-list*	*Average annual cost of consultant salary per bed*
Manchester	56,734	£28.5
Sheffield	51,960	£33.6
N.W. Metropolitan	36,447	£45.8

On March 10 the following facts emerged in answer to a question on staffing of beds for mental illness:

Region	*Beds*	*Consultants as whole-time units*
Manchester	13,019	18
Birmingham	13,758	36
N.W. Metropolitan	11,848	42

These contrasting figures are extremely difficult to relate to community needs, for social conditions would suggest the probability of a higher morbidity incidence in those regions with the lowest consultant ratios. It is extremely difficult to hold the Ministry of Health responsible, for ten years regional boards have been at liberty to devote each year what was considered an adequate sum to provide for the expansion of consultant staffing. The total allocation from the Ministry may have been inadequate but the method of spending this total was within the boards' jurisdiction.

In many regions very powerful medical advisory committees have had great influence on board policies.

We in the profession have failed to equate consultant supply to the needs of the population. The Ministry has failed to give money, encouragement, and advice in the matter. It is essential that action should be taken to break this impasse. An impartial committee, under a lay chairman, should review the situation speedily and make proposals to the Ministry and regional boards which will ensure a balanced medical service and help to eradicate an unsavoury situation which is not inherent in a national health service.

Central Middlesex Hospital,
London, N.W.10

HORACE JOULES

*** Our parliamentary report on p. 748 gives regional figures for consultants and staffed beds.—ED. L.

A FUNCTIONAL NECESSITY

SIR,—The answer to the "registrar problem" is quite simple. After an aspiring specialist has completed the senior house-officer, registrar, and senior registrar appointments he should be eligible to be appointed "consultant." This appointment would be similar in status to that of assistant surgeon or physician in the teaching hospitals before 1948. There must be enough of these appointments to absorb every senior registrar. "Weeding out" should be done at registrar level. The qualifications and experience necessary for "consultant" would be those now found in senior registrars in their third or fourth year or in the better S.H.M.O. appointments. The salary scale would by present standards be in the range £1700 to £3000. At the age of 45 years or after 20 years in the specialty a limited number of consultants—say, 20%—who had exceptional qualifications or who had made valuable contributions would be eligible to apply for the appointment of senior consultant with a salary range of £3000 to £4000. This scheme would:

(1) Remove unsuitable specialist material at a level when it is not too late to go into general practice or allow aspiring general practitioners to take registrar appointments before going into general practice.

(2) Solve the problem of redundant senior registrars.

(3) Remove the unfair gap that sometimes exists between the well-qualified S.H.M.O. and the well-qualified consultant of about 35. Often whether a man is an S.H.M.O. or consultant is a pure gamble.

(4) Remove the iniquities of the merit-award system.

I might add that at the moment I have no axe to grind since I am a fairly contented S.H.M.O.—a rare bird, so it appears. I should rather wait a while as an S.H.M.O. at my present hospital than be a consultant at certain hospitals I know. But, of course, if my suggestions were put into practice I should be even more content.

Leicester

HUMPHRY B. KIDD

TREATMENT OF BREAST CANCER

SIR,—In your leading article of Feb. 1, you say that "a strong challenge [to Professor McWhirter] now comes from the Mayo Clinic" where[1] in patients treated mainly by radical mastectomy in 1941–47, the five-year survival was 59.3% as compared with 48.1% in McWhirter's group treated in the same period mainly by simple mastectomy and irradiation. You also say that "comparison between the figures from the Mayo Clinic and those from Edinburgh is difficult", because in the Mayo Clinic series cases not operated upon were not recorded whereas "257 inoperable cases were included in McWhirter's results."

In his article,[2] referred to by Berkson et al. of the Mayo Clinic, McWhirter breaks down his total experience into 3 categories:

1. Operable (by ordinary standards for radical mastectomy): 1063 cases, 58% living 5 years. (This figure is almost the same as the 59.3% survival-rate of the Mayo Clinic's radical mastectomy series.)
2. Locally advanced: 546 cases, 30% living 5 years.
3. Distant metastases: 273 cases, 4% living 5 years.

It is clear that Berkson et al. compared the results obtained in the Mayo Clinic's operable cases with a group of McWhirter's cases that included both locally advanced (inoperable) and operable cases. The result, therefore, is not (as you state) failure to consider "the 257 inoperable cases." It is total disregard for McWhirter's 546 patients with advanced and inoperable local disease.

Reference to McWhirter's tables and to the Mayo Clinic's tables of five-year survivals shows that similar results were obtained by the two different methods of therapy.

	Five-year survivals	
	Mayo Clinic	*McWhirter*
All operable cases	59.3%*	58%
All operable cases under 65 years of age	58.9%*	60%

* Operative deaths not included.

Again it appears that in breast cancer the selection of cases for comparison has more influence on published results than the method of treatment given.

Department of General Surgery,
Cleveland Clinic,
Cleveland, Ohio

MITRAL VALVOTOMY AND PREGNANCY

SIR,—In their paper on mitral valvotomy and pregnancy, Dr Wade and his colleagues raise a number of points concerning which our experience may be of interest In their series of 12 cases of valvotomy during pregnancy there was 1 maternal death, a number of serious complications, and 4 cases in which stenosis of the mitral valve was not severe 2 cases of valvotomy during pregnancy were reported,[1] and of our 400 consecutive patients subjected to mitral valvotomy in the past seven years, 10 were pregnant at the time of operation In this series of 10 there have been no maternal deaths and no important postoperative complications The 3rd patient had relatively mild stenosis (2 cm), and it was her case which prompted a review of the criteria for operation These two series are small but the published cases now number 97, and the fact that there have been 2 maternal deaths and some serious complications suggests that there may be an increased risk in operation at this time In this particular age-group (under 45) and with sinus rhythm our operative mortality has been less than 1%

In regard to the 4 patients in whom the stenosis was not severe, Dr Wade and his colleagues state that operation would not have been advised apart from pregnancy and these patients could have been managed medically They also state that if symptoms are severe enough and the valve is technically suitable, valvotomy is the treatment of choice. However, as they indicate, the increased blood-volume and cardiac output which occur in pregnancy greatly increase the resistance to blood-flow at the mitral valve Therefore symptoms during pregnancy may be out of all proportion to the stenosis and are, in themselves, an unreliable guide to the benefit which may accrue from operation since it may not be possible to enlarge significantly an orifice which is only moderately stenosed In our opinion, the criteria for recommending operation during pregnancy are a history of progressive dyspnœa before pregnancy and objective evidence of tight stenosis—that is, an electrocardiographic pattern of right ventricular hypertrophy and radiographic evidence of enlargement of the pulmonary artery and its main branches Basal transverse lines from distended lymphatics and an increased pulmonary arterial pressure as recorded by cardiac catheterisation during pregnancy are as unreliable as the severity of the symptoms

The point as to whether the valve is " technically suitable " is also worthy of consideration because, in our experience, the concept of the " pliant valve " is open to question[2] It is true that it is among those with " clear signs "—i e , a loud first heart sound and opening snap and a rumbling mid-diastolic murmur—that valves readily amenable to valvotomy will be found, but in this group there will also be many with tough, rigid valves in whom it is difficult to achieve a satisfactory result All that can be done is to ascertain that the degree of stenosis is considerable and then the patient must have what amounts to an exploratory cardiotomy Fortunately, in most cases, despite a rigid valve, a worth-while degree of splitting of the commissures can be obtained, especially with the aid of a transventricular dilator, and substantial benefit follows However, it must be remembered that even a technically successful valvotomy usually leaves a valve which is far from normal, and this will account for the fact that fairly severe symptoms may recur during pregnancy despite operation

The natural reluctance of a mother to be parted from her infant in its first months is, as we have emphasised, in favour of valvotomy during pregnancy in suitable cases to avoid postponement of the operation for more than a year from the initial examination

In summary, then, surgery during pregnancy is undesirable unless the evidence for tight stenosis is based on severity of symptoms before pregnancy began or objective signs of longstanding pulmonary hypertension but if these are present there is no contraindication t operation and usually the time is domestically convenient

Edinburgh RICHARD TURNER

MODIFIED TRACHEOTOMY TUBE

SIR,—In your issue of March 15 (p 569), Dr Frank Wilson describes a modified tracheotomy tube, the essential feature of which is an opening on the convexity of the outer cannula that allows, when the anterior aperture is occluded, re-establishment of the natural airway through the larynx Tubes of this type were made for and used by me over twenty years ago in the treatment of laryngeal diphtheria[1]

In those days of fairly frequent tracheotomy some children had difficulty in dispensing with the tube, owing to spasm of the larynx or to fear of choking The special open-back cannula was devised to allow them practice in natural breathing while retaining the safeguard of the tracheotomy tube Somethimes this took several weeks, and one child of two years wore his tube for almost a year before discovering that he could do without it No special occluder was used one simply covered the aperture with a piece of adhesive plaster

I still have the tubes in my possession, but with the decline of diphtheria have had no occasion to use them for a very long time

Infectious Diseases Hospital,
Paisley WILLIAM NAPIER.

INFANTILE GASTROENTERITIS

SIR,—I am pleased to see that Dr Giles (March 8) acknowledges my position in the matter of the relationship of *Escherichia coli* to gastroenteritis, but I do not think I misrepresented him, although I am prepared to accept that he has changed his views since 1948 when he and Dr Sangster wrote[2] " In view of our failure to demonstrate the pathogenicity of the agglutinable coliform, the possibility remains that the organism is merely a constant concomitant of a hitherto undiscovered virus, comparable with the presence of *B suipestifer* in the virus disease of hog cholera All efforts to demonstrate such a virus have as yet been unsuccessful ", and again, " Recovery of the previously described type of *B coli* in the fæces of an infant suffering from diarrhœa affords, in our opinion, strong presumptive evidence of at least one variety of primary gastroenteritis, *but whether its presence in over 90% of cases is of true ætiological significance remains to be seen* " (my italics)

Dr Giles asks what are my reasons for doubt, despite the published work of the past ten years Most of this work merely aims at confirming the presence of *Esch coli* serotypes in the stools without attempting to explain their presence there I recall no fundamental work on the normal bacterial flora of the infant gut stemming from this When does this flora change and why? Does it differ materially in the breast-fed or bottle-fed infant? *Esch coli* is regarded as a normal bowel inhabitant what factors predispose to a change in its character? Why should it apparently behave so differently from other known bacterial gut pathogens, such as the salmonellæ and enteric groups?

For a fæcal-borne pathogen to travel through the air with the speed ascribed to it seems incredible, unless all rules of hygiene are disregarded The infant's stools are fluid and are not normally left long enough to dry, and dry dust seems the only valid medium Indeed Hutchinson[3] states that there is insufficient evidence to show that infection spreads in hospital by means of ward dust

[2] Turner, R W D , Fraser, H R I *ibid* 1956, ii, 525, 587

[1] Napier, W *Lancet*, 1937, ii, 673

[2] Giles, C , Sangster, G *J Hyg , Camb* 1948, 46, 7

A significant proportion of infants are symptomless excretors why should not this represent the normal? If not, what causes the change? Enteric viruses have now been recognised (e g, Echo group, poliomyelitis), and to my mind such a virus seems to explain the rapid spread and explosive outbursts better than a bacterium.

There are many other questions to be answered I can only echo Lord Evans' words[4] "It is difficult to be entirely convinced that what appears on the culture plate in the laboratory is necessarily the same as happens in the patient"

NYLON-DARN REPAIRS OF HERNIÆ

SIR,—Mr Doran (March 22) makes a plea for the scientific approach to surgical problems and immediately takes the very unscientific step of distorting the evidence to suit his argument. The claim which he attributes to me, that a chronic sinus with monofilament nylon is almost unknown, is a travesty of the statement which I made (Feb 22)—which was that a chronic sinus following the use of the finer sizes of monofilamentous nylon is almost unknown in my experience He claims that my findings were diametrically opposed to those of Mr Marsden (March 8)—and Mr Marsden himself appears to think so too—but as I see it we both found that thick monofilamentous nylon not infrequently caused chronic sinuses Indeed, the findings of all your correspondents on this subject are compatible with my observation that thick nylon sometimes causes sinuses and thin nylon does not

It appears, therefore, that the premise on which Mr Doran's disputation is based is false

Manchester
HERBERT HAXTON

THE DOCTOR'S ATTITUDE TO HIS PATIENT

SIR,—In his letters of March 1 and 22, Dr Ryle criticised Dr Clyne (Feb 1) and castigated Dr Pasmore (March 8) for views which he states "insist upon a subjective approach which withdraws psychiatry from the arena of science" He is all for "detached scientific observations of the cause of neurosis"—and who is not?

But the only instrument of the would-be detached scientific observer in this field, both for investigation and treatment, is his own personality, imperfect though that may be To use this as effectively as possible the personality must be studied, altered, and allowance made for individual bias How this can be done other than subjectively I do not understand

Although Dr Ryle writes in his first letter that "the doctor's personality plays a very important part, and should be understood", he underestimates the importance of this vital fact, and his belief that only some doctors need attempt to adjust personality difficulties is a delusion Doctors do not spring at birth like Athene from the head of Zeus, free from the disabilities of the unconscious mind We are made from the same stuff as the rest of humanity

By ignoring this Dr Ryle is not advancing to the scientific goal which he seeks, but is maintaining what is now an outmoded obscurantism, based on his earlier training, as Dr Pasmore deduces in his letter

Sittingbourne, Kent
F M MALLINSON

BED REST, THROMBOSIS, AND EMBOLISM

SIR,—Your leading article of March 1 surveys venous thrombosis and pulmonary embolism in patients at rest in bed after operation Like most British writers on the subject, you do not refer to pulmonary emboli that arise from unsuspected leg-vein thrombosis in patients who are not confined to bed, but who are walking about and doing their ordinary work Long recognised in America,[1] these are common enough in this country to be clinically important, and any attempt to explain pulmonary emboli must take them into account. In concentrating on the postoperative cases, which are only part of the picture, it may be that some ætiological clue is being overlooked Small pulmonary emboli in ambulant people are usually diagnosed as pneumonia (It is not so long since small postoperative emboli were similarly misinterpreted) Large ones, if not immediately fatal, may be taken for painless myocardial infarcts I record in the accompanying table details of 11 cases of this type referred to me during the past six years All had multiple emboli, and the legs were outwardly normal, except for varicose veins in case 9 Cases 1–4 have been published elsewhere.[2]

PULMONARY INFARCTS IN AMBULANT PATIENTS

Case no	Age	Sex	Clinical features	Outcome
1	47	M	Dyspnœa	Necropsy multiple emboli, thrombosis left soleus
2	50	F	Dyspnœa, triple rhythm, E.C G of acute cor pulmonale	Necropsy multiple emboli, thrombosis both popliteals
3	49	M	Pain, dyspnœa	Necropsy multiple emboli, thrombosis both femorals
4	47	M	Recurrent pneumonia ×5	Cure by femoral-vein ligation
5	66	F	Recurrent pneumonia	Necropsy, multiple emboli, thrombosis left popliteal
6	71	M	Pneumonia	Responded to anticoagulants
7	75	F	Dyspnœa	Necropsy multiple emboli, thrombosis left posterior tibial
8	66	M	Pneumonia	Necropsy multiple emboli, thrombosis femoral
9	36	M	Pleurisy ×2, lung abscess	Cure by ligation of common iliac vein
10	54	M	Pneumonia ×2	Cure by ligation of inferior vena cava
11	43	M	Pain, dyspnœa, 3 attacks, triple rhythm	Responded to anticoagulants

I have not included 16 patients admitted to my wards during the same period in whom pulmonary embolism had arisen, while they were ambulant, from an obvious swollen leg These were not severe, and rarely recurred Since diagnosis presented no difficulty, anticoagulant treatment was started at once

Pulmonary infarction from small emboli is marked by pain, hæmoptysis, and fever, with pleural rub or consolidation on examination Pneumonia suggests itself, but if the symptoms recur after an interval, and particularly if they change sides, an embolic origin must be considered and must not be discarded, as so often it is, because of the apparently normal legs The expected response to antibiotics is of course lacking The appearance of the chest radiograph is often inconclusive Large emboli differ in producing severe dyspnœa, jugular venous distension, and triple rhythm, without local signs in the lungs clinically or radiologically The electrocardiogram may help here in case 2 it was diagnostic, and in case 11 right bundle-branch block was a valuable pointer

When diagnosis was made I have relied on anticoagulants in the first instance, but recurrence after withdrawal of treatment has compelled interruption of veins in cases 4, 8, and 10 It is clear that some of these patients must have either permanent anticoagulant treatment or venous ligation No effective treatment had been undertaken in those who died

Rest in bed played no part in the production of these invisible thromboses, which had such serious effects, nor did other factors that have been claimed to operate, such as sitting in cramped positions in cars or aircraft No instance of malignant disease appeared either in necropsy or follow-up To describe such thromboses as " spontaneous " is to beg the question of their origin to explain them might throw light on the even more serious problem of postoperative emboli

Carshalton, Surrey

C P PETCH

ESSENTIAL FATTY ACIDS, LIPID METABOLISM AND ATHEROSCLEROSIS

SIR,—In your issue of Feb 15 Dr Kinsell and his colleagues discuss the serum-cholesterol-lowering effect of certain fatty acids and make the surprising statement (p 338) that we (Keys et al) and Ahrens et al [1] [2] " have advanced the hypothesis that double bonds furnished by fatty acids are responsible for the effects observed—i e , sufficient oleate would be quite as effective as linoleate or arachidonate Our studies do not support such a hypothesis "

As a matter of fact, this question of effect or lack of effect on serum-cholesterol of dietary oleic acid has been a matter of friendly but rather vigorous controversy between Ahrens et al and ourselves for the past year, notably at major symposia organised by the American Medical Association Council on Foods and Nutrition (New Orleans, March 15, 1957) and by the American College of Physicians (Boston, April 10, 1957), and at the Cleveland Symposium on the Chemistry of Lipides (May 7, 8, 1957)

Shortly before the article by Kinsell et al appeared, the Cleveland Symposium was published [2] and in this Ahrens et al discuss our publications and views at some length and state that we (Keys et al) " conclude further that the mono-ethenoid acids (almost entirely oleic acid) are neutral or totally lacking in effect, since a term describing the content of oleic acid in the dietary fat need not appear in the prediction equations "

We have summarised [3] our analysis of the results in 41 sets of controlled dietary comparisons, each involving 12 to 27 men on each of two diets differing in fats, which yielded the prediction equation for the response of serum-cholesterol concentration to a dietary change in fats

$$\widetilde{\Delta}\ \text{Chol} = 2\ 73(\Delta \textsc{s}) + 0\ 01(\Delta \textsc{m}) - 1\ 31(\Delta \textsc{p})$$

where S, M, and P are the percentages of the total diet calories provided from saturated, mono-ethenoid, and poly-ethenoid fatty acids, respectively, and the Δs are the differences between the two diets being compared We noted that " The contribution of the term for ΔM is statistically non-significant and recomputation with this term omitted yielded the equation

$$\widetilde{\Delta}\ \text{Chol} = 2\ 74(\Delta \textsc{s}) - 1\ 31(\Delta \textsc{p}) \text{ "}$$

Further, we stated, " Whether the mono-ethenoids (essentially oleic acid) have any effect is uncertain, but if there is an effect it is certainly small " Full details of the diets, methods, findings, and statistical analyses in these experiments covering the period 1951–56 have been published [4] [5]

Kinsell et al , besides misquoting us, report two instances in which they compared the effects on serum-cholesterol of oleic acid and linoleic acid in the diet

In the first, in a boy aged 19, at the end of three weeks on a formula diet containing 80 g of ethyl oleate daily the serum-cholesterol level was about 65 mg per 100 ml higher than at the end of two weeks when the formula contained 80 g of ethyl linoleate

In the second, a diabetic patient on a similar formula diet had a serum-cholesterol of 270 mg per 100 ml at the end of a week when the daily diet contained 75 g of trilinolein, 235 mg at the end of two weeks in which the diet contained 75 g of triolein instead of the trilinolein, and 297 mg at the end of three weeks when 75 g of ethyl oleate was substituted

We regret that these observations scarcely qualify as acceptable confirmation of our own findings and interpretation, though they are not in opposition

More to the point are two new sets of data from our own controlled dietary experiments which will be reported in full in due course but may be mentioned here

First, a switchback dietary experiment on 22 men, rigorously controlled for six weeks, conclusively showed no effect on serum-cholesterol from substitution of 68 g of oleic acid glyceride daily for 612 calories of carbohydrate or from the reverse substitution [6]

Second, we now have 12 additional sets of dietary comparisons, each involving 5 to 25 men on each of two diets differing only in the kind of fat or in the isocaloric exchange of fat for carbohydrate in the diet Least-squares multiple regression analysis of the data in the same manner as reported previously [4] [5] produced coefficients in a prediction equation statistically indistinguishable from those found in the earlier 41 sets of experimental comparisons, and again the mono-ethenoid (oleic acid) variable makes no statistical contribution (i e , zero effect)

The conclusion is, as before, that saturated fats raise the serum-cholesterol level when isocalorically substituted for carbohydrate, that polyunsaturated fatty acids lower it, and that about 2 g of linoleic acid is needed to offset the effect of 1 g of stearic or palmitic acid Finally, and again as before, we conclude that oleic acid has no significant effect in either direction, oleic acid glyceride is substantially equivalent to simple carbohydrate in effect on serum-cholesterol

We have noted that oleic acid accounts for practically all of the mono-ethenoid fatty acid in the great majority of natural food fats and oils Rape-seed oil, which contains up to half of its fatty acids in the form of the mono-ethenoid erucic acid (a 22-carbon mono-ethenoid, docos-13-enoic) is an exception We have no experience with rape-seed oil, but the data in the recent report by Linko,[7] though inadequate for exact computation, suggest that erucic acid, like oleic, is " neutral " in respect to effect on the serum-cholesterol level in man

Ahrens et al [2] admit that their data are in conformity with computations from our prediction equation (published before their data appeared), but object that, " Keys' prediction could have been expressed just as accurately, and less mysteriously, in terms of iodine value of dietary fat " This is just as palpably erroneous as the misquotation of Kinsell et al The iodine value is, of course, merely a measure of the number of double bonds in 100 g of fat, whereas our equation ignores the double bonds in mono-ethenoid fatty acids and, in any case, refers to the amount of fat calories as a percentage of calories from all sources in the diet

Ahrens et al may have been misled by the fact that in their experiments, in contrast with our own, they usually deal with the same amount of total fat and vary only the kind of fat In that situation there is often a rough relationship between the iodine value and the expression 2S−P, which is an approximation to the right-hand term in our equation given above But even when the total fat is constant the iodine value does not correspond precisely with our formulation

Consider a 3000-calorie diet in which there is a total of 133 g of fatty-acid glycerides, half being saturated and half being linoleic acid Let us now change the diet only by replacing these fatty acids with 133 g of oleic-acid glyceride (i e , triolein) Note that fats yield

7 Linko, E *Acta med scand* 1957, 159, 474

1200 calories of the total 3000, or 40%, in both diets, and, in our terms, we have values of S=20 and P=20 with the first diet and S=0, P=0 with the second The iodine value will be identical in the two cases (=86) and, according to Ahrens et al , there will be no change in serum-cholesterol But the equation based on our experimental results predicts a serum-cholesterol change

$$\Delta \text{ Chol} = 2\ 74(0-20) - 1\ 31(0-20) = -29,$$

i e , on the average, the serum-cholesterol concentration will fall by 29 mg per 100 ml on the second diet.

Finally, we may consider a third diet which differs from the first only in that the total fat is only 67 g (20% of total calories) The iodine value is still 86 in both diets Ahrens et al apparently predict no change, or at least they provide no clue as to what may happen But our equation predicts

$$\Delta \text{ Chol} = 2\ 74(10-20) - 1\ 31(10-20) = -14,$$

i e , changing from the first to the third diet will, on the average, produce a fall of 14 mg per 100 ml

In view of the fact that the great current interest on these points seems to be matched by an equal degree of confusion in many quarters, we should point out that the prediction equation refers to the average changes in serum-cholesterol to be expected in men without a high serum-cholesterol within two to four weeks after a dietary change Larger responses may be expected in hypercholesterolæmia and also, perhaps, with dietary differences maintained for very long periods of time And, of course, there is no place here for speculations about "essential-fatty-acid deficiency"

REDUCTION OF CIRCULATING LIPIDS

SIR,—With reference to the article by Dr Oliver and Dr Boyd[1] your readers may be interested to hear of our results in a similar therapeutic trial[2] with 2-phenyl-*n*-butyric acid amide *

Of 15 men with considerable hypercholesterolæmia, 12 had had a myocardial infarction between six weeks and a year previously, but had no signs at present of cardiac failure or of angina 1 had essential hypertension, another had essential hypercholesterolæmia without clinical manifestations, and 1 had hypercholesterolæmia with xanthoma tuberosum on the fingers and elbows The ages of the patients varied from 36 to 63 (average 50 6)

The dosage of 2-phenyl-*n*-butyric acid amide was 1 g every eight hours All patients were carrying on their usual occupations, no special diet was given, but they were asked to be careful not to put on weight. 1 patient received the treatment for four weeks, 3 for two months, and the others for from three to five months In 10 of the 15 patients, plasma-cholesterol level was reduced by 20 mg or more per 100 ml The initial mean total plasma-cholesterol in the 10 patients who reacted favourably was 346 mg per 100 ml., this dropped to 310 mg after giving the drug The mean initial absolute level of β-cholesterol was 310 mg per 100 ml., dropping to 258 mg after treatment (the β-cholesterol level was determined by analytical chemical methods after elution of the fraction from the paper after electrophoresis)

The average total plasma-cholesterol among healthy men of European Jewish origin in Israel in the age-group 40–60 is 220 mg. per 100 ml , and of β-cholesterol 180 mg , taking these levels as 100%, our results for the 10 patients were a drop in total cholesterol from 157% to 131% and a drop in β-cholesterol from 162% to 143%

The effect of 2-phenyl-*n*-butyric acid amide seems to be greater in patients with a high initial level of plasma cholesterol, 4 of the 5 patients who did not react to the treatment (and only 1 of the 10 who did) had an initial plasma-cholesterol less than 300 mg per 100 ml

Like Dr Oliver and Dr Boyd, we found hardly any change in the ratio between α and β cholesterol, even where there was a significant fall in total cholesterol We have noted this in other therapeutic trials for lowering the lipid levels, and it seems that the ratio of α to β cholesterol is one of the most stable factors of the lipid patterns

In none of the 15 patients did the lipid levels rise We infer that 2-phenyl-*n*-butyric acid amide has a genuine, though not great, cholesterol-depressing effect Our results are not so favourable as those of the French and Italian clinical workers,[3-6] but we believe that n-phenyl-*n*-butyric acid amide does have some effect, especially when the plasma-cholesterol is very high

CORONARY-ARTERY DISEASE

SIR,—In your leading article of March 22 you quote the statement that "in the healthy organism fibrinolysis is in a dynamic equilibrium with the fibrin-depositing coagulation process", the implication being that so much has been established. This is rather misleading, since what is quoted is an intelligent speculation first put forward to my knowledge by Nolf in 1908, and adopted as a working hypothesis by many workers, including Astrup However attractive the concept may seem it should be made clear that it is unsupported by direct evidence

It will be a pity if the observations of various workers on fibrinolysis in vitro, including the effect of fat, be pressed into speculative dynamic hypotheses subsequently to be quoted as if proven Such a tendency is likely to retard and not to advance knowledge

G R. FEARNLEY

RECTAL METHYLPENTYNOL IN LABOUR

SIR,—The place of methylpentynol in labour is now well recognised, but rectal administration receives no mention This route has been found effective in over 5000 women admitted to the Birmingham Maternity Hospital in the past three years

This method was first tried when it was noted that the patient who most often vomited the oral capsule was the nervous primigravida—the patient whose apprehension it was hoped to relieve, not increase Bourne[7] reported that 8% of patients vomit the capsule, but a second dose is usually retained By use of the rectal route, increase of nervous tension from this vomiting can be avoided without loss of the drug's efficiency

Methylpentynol is given half an hour after an enema to a patient in early established labour The usual dose is 750 mg (i e., 3 capsules), inserted with the finger as far as possible beyond the anal margin. Occasionally in a very nervous primigravida 1 g of methylpentynol is given, and, again uncommonly, the dose may be repeated in not less than three hours When the patient's anxiety is associated with painful contractions it is our practice to give 100 mg of pethidine hydrochloride intramuscularly with the initial dose, for methylpentynol does not relieve pain.

The drug is as efficient when given rectally as it is by mouth. The clinical impression is that labour is shortened and the incidence of postpartum hæmorrhage is not increased

If it is given late in the first stage, pressure of the head during the second stage will at times expel a proportion of the dissolved capsule and drug from the anus As it is a brilliant green it is easily distinguishable from meconium

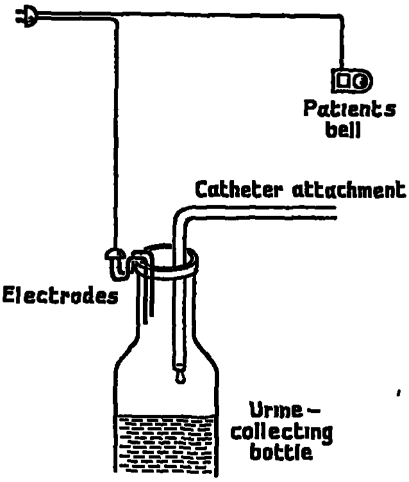
No ill effects have been seen, either generally or locally in the rectum The infant appears unaffected

This method has been of value in general practice, where constant supervision in the early stage of labour is not always possible

University of Birmingham W L **Whitehouse**

AUTOMATIC SIGNAL FOR URINE-COLLECTING BOTTLES

Sir,—It is sometimes hard for nurses, especially during busy night-watches, to cope with the rapidly filling urine-collecting bottles of polyuric patients with indwelling catheters An automatic device for calling the nurses' attention to a full bottle would therefore be of value, and the following signal system was constructed



Two electrodes, connected to the regular patient-bell system (working under 24 volts) are put into the upper part of the urine-collecting bottle (see accompanying figure), as soon as the urine reaches the electrodes, the electric circuit is closed (by electrolysis of the urine), and the bell rings—incessantly, of course, thereby differentiating this call from the normal one-ring call by patients

Our nurses appreciate this device Urine collections are now more accurate, and ward hygiene has improved

I am grateful to Mr J Fraenkel, the hospital electrician, for his advice

Shaarei Zedek General Hospital,
Jerusalem J **Leurer**

NO PEACE FOR THE PATIENT

Sir,—" Ex-Patient " (March 22) lists forty separate calls on her attention during the hospital day, but does not describe how sleep is murdered at night too A recent extended visit to hospital (when I had every reason to be grateful for the excellent care which I received) opened my eyes, both figuratively and in fact

The main causes of the disturbance seem to be the clanging and squeaky trolleys (which are apparently indispensable to nurses in the course of their duty), and the constant shouting of the senile and demented Could not the hospital trolleys be oiled, and the senile all be placed together in one ward? In order to fill a ward, medical and surgical patients might have to go together, but, after all, this is supposed to be an age where barriers are breaking down

While the vast majority of patients do not suffer physically at all under these nocturnal disturbances, the effect on children (and there is usually one in every ward in a large general hospital) must surely be bad

The Medical School,
Manchester Valerie **Frazer**

P A S AND THE PATIENT

Sir,—We should like to join the discussion which has followed our article on outpatient P A S therapy [1–6]

Our main aim was to indicate the *size* of the problem presented by the failure of patients to consume their prescribed P A S Whether the default-rate is 50% (as found by us in the 151 members of a complete outpatient population), or whether it is 25% [7] or 22% [5] (as found in more selected groups), the conclusion must be the same patients who fail to take P A S form a very substantial proportion of those so treated We cannot believe that patients vary so much from district to district that any physician could afford to disregard this fact when deciding to use oral medication The difficulties of providing an alternative to long-term streptomycin and isoniazid [2,5] are freely admitted, but they must be weighed carefully against the possible failure to take P A S The toxic effects of streptomycin, in our experience, can partly be avoided by giving equal parts of streptomycin and dihydrostreptomycin, and this is our practice in patients over 50 years of age If oral therapy is chosen, then every encouragement and explanation must be given to the patients, and urine tested on frequent and unexpected occasions

Our second aim was to draw attention to a modification of the ferric-chloride test which is simple enough to use as a routine in outpatient departments and is, when performed exactly as described, sensitive enough to detect P A S taken in full dosage whilst minimising confusion with the usual doses of aspirin A test that is too sensitive would react strongly with the urine of patients who have taken aspirin or salicylate, inadequate doses of P A S would also give positive results At the same time we consider that the problem of occasional false results is of little importance compared with the default-rate revealed

The detection of calcium B-P A S in the urine is affected by the dosage schedule and dose/test time intervals as indicated by Dr Lauener and Dr Friedrich [6] During the period of our trial the daily prescriptions were 14 g of calcium B-P A S or 10 g of P A S We have felt these to be the minimum desirable doses At this dosage of calcium B-P A S the proposed increase in sensitivity [6] is unnecessary and in fact undesirable in its present form the test may well be negative if patients are taking very low doses of calcium B-P A S, but we feel this to be an advantage We always prescribe oral P A S in two equal daily doses at twelve-hour intervals, as you recommend,[2] and therefore our single dose of calcium B-P A S was always twice that mentioned by your correspondents [6] During our trial calcium B-P A S was prescribed in 43 cases In 21 (49%) a positive urine test was found and in 9 cases the test was still positive at ten to twelve hours after ingestion It thus seems clear that a 7 g dose of calcium B-P A S is capable of giving a positive reaction to our ferric-chloride test, which should be of sufficient sensitivity to be of practical value to those physicians who continue to prescribe this drug We ourselves are not convinced that calcium B-P A S is as effective in preventing isoniazid resistance as is P A S, and for this and other reasons we no longer use it

However, to return to the main argument, even if we assumed that all our negative tests with calcium B-P A S were false (which we do not believe), the proportion of defaulters among our patients is lowered only from 50% to 36% It is evident that all published work on this subject has revealed a high default-rate in taking P A S

5 Leggat, P C *ibid* p 1283
6 Lauener, H, Friedrich, T *ibid* March 15, 1958, p 592
7 Simpson, J McD *Tubercle*, 1956, 37, 333

Whereas, in the case of this drug, the unpleasant side-effects provide an adequate reason, we believe that the issue may be much wider A similar picture might well be revealed in the medication for diseases other than tuberculosis

Finally, may we express our general disapproval of eponyms? In fact I D P W was responsible for the modification of the standard ferric-chloride test, so to call it "Dixon's test" would be doubly wrong

A LOW-RESISTANCE RESPIRATORY VALVE

SIR,—I must take exception to the comments of Dr Theron and his colleagues (Feb 22) upon the low-resistance respiratory valve described by my former colleagues[1] It seems that Dr Theron and his colleagues have never seen such a valve, and so their comments on its suitability, however valid, are out of place Furthermore, it is not true to say "The only valve of comparable (sic) resistance is that described ", had they plotted the published resistance of Bannister and Cormack's larger valve in their fig 1, they would have found that it falls between the curves (5a and b) for their own doubtless excellent valve

D J C CUNNINGHAM

LUNG RESECTION FOR BRONCHIECTASIS

SIR,—Your annotation of March 22 is a gross misrepresentation of the present position of surgery in bronchiectasis One has come to regard pulmonary resection for localised bronchiectasis as a most rewarding adjunct to treatment in a substantial proportion of cases, and it comes as a rude shock to see you dismiss it as "rarely desirable"

You base your opinion on the grounds of (1) high operative mortality, prohibitive in the case of pneumonectomy, (2) high incidence of morbidity, in particular postoperative collapse, (3) loss of pulmonary function, and (4) extension of bronchiectasis in the residual lung You further state that the results of conservative treatment are favourable

In a personal series of 109 cases, including 17 bilateral cases and 6 pneumonectomies, there were no operative or postoperative deaths One patient died a year after extensive bilateral surgery from pneumonia and respiratory failure About half of the patients were under 20, and all were operated on because of failure of medical treatment There was no case of persistent postoperative atelectasis Only patients who were not symptom-free for a year after surgery were followed up for longer periods, the great majority of patients have been discharged Of the remainder, in no case has further bronchiectasis been shown to develop

Gross localised bronchiectasis (which may include as much as both lower lobes, middle lobe, and lingula) is surely accompanied by loss of function in the diseased areas, and its removal results in little or no further loss of function Pulmonary efficiency may be improved

Finally, you state that no modern advance in technique is likely to affect the most important factor in the alleged failure of surgery—namely, the inevitable distortion of the bronchial tree and interference with the drainage of the remaining bronchi I am aware of no evidence to show that bronchial distortion, if it occurs, is a cause either of bronchiectasis or of impaired bronchial drainage

I submit, Sir, that the figures I have outlined are more in keeping with the experience of a modern chest service than those you quote, and which you admit are unusual in the very high average age of the patients reviewed. It would be a disservice to patients suitable for surgery if they were instead to be condemned to a life of recurrent exacerbations and increasing respiratory disability

CLINICAL GERIATRICS

SIR,—Dr Pappworth (March 22) asks in effect whether the clinical signs of any disease differ in elderly as compared with younger patients The answer, I would suggest, is that very often they do, though the differences are greater in those in their 70s and above. To mention but a few: elderly people with pneumonia seldom exhibit any pyrexia, cardiac infarction is common and frequently "silent", and many disorders come to notice only because of mental symptoms which are, however, not evidence of senile dementia It is important that these many differences should be recognised, and the limits of normality at various ages should be better understood

But geriatrics is also concerned with the many ways in which elderly and partially disabled people can be rehabilitated and helped afterwards to live an independent existence outside hospital Those who have not seen this taking place can scarcely believe how many, on being admitted to an active geriatric department, can be made well enough to leave hospital This is achieved not by administration, but by hard work in the clinical field. Should not geriatrics therefore be taught as a branch of medicine by those who practise it, so that we may at last be rid of the attitude of mind which classes patients over 70 as "senile" and thus unworthy of our best attentions?

Ipswich

[illegible]

SIR,—Dr Pappworth does not seem to have read your annotation of March 1, which mentions a number of ways in which the symptoms and signs of disease are modified by age If he consults the current issue of The Practitioner he can read a short paper describing a series of gastric ulcers, proved at necropsy, but not presenting their usual clinical features in old people The same journal also records a group of patients with new growths whose signs and symptoms were cloaked by mental symptoms. The special effects of hæmorrhage in the elderly have been described by Bedford[2], the organic basis of confusional states in the elderly by Flint[3], hypoglycæmia and confusion by Helps[4], and Vince[5] has written on clinical pitfalls in the elderly and so have others elsewhere.

Dr Pappworth mentions an age of 60 for a hypothetical patient This is rather on the young side for a typical geriatric case A survey at Queen's Hospital, Croydon, showed that 34% of the patients were between 80 and 89, while 9% were over 90 The administrative problems, which Dr Pappworth says he can understand, arise because the clinical aspects of disease change as the patient grows older For necropsy proof of this I would refer him to a series of papers in Geriatrics.[6]

Clinical instruction in geriatrics is also desirable because the limits of normality change with age My own book on Old Age was one of the first to give detailed examples of this Holborn and Pemberton have also provided data in *The Health of the Elderly at Home*

---

In fact, there is now recorded a considerable body of material dealing with clinical and pathological aspects of disease in old age, which should be brought to the notice of students—the more so since some of their seniors are not familiar with it

London, S W 16 TREVOR H HOWELL

5-BROMOSALICYLHYDROXAMIC ACID FOR TUBERCULOSIS

SIR,—The tuberculostatic action of 5-bromosalicylhydroxamic acid was described by Urbanski and his colleagues [1] More recently Hornung et al [2] have reported that the compound, in a daily dose of 3 g, is as effective as 10 g of *p*-aminosalicylic acid (P A S) in delaying the development of resistance to isoniazid in patients suffering from tuberculosis, They also stated that 5-bromosalicylhydroxamic acid was much better tolerated than P A S It seemed, therefore, that it would be interesting to investigate these claims, and the results of some preliminary experiments may be summarised

In vitro we have confirmed the observations by McIsaac and Williams [3] that high concentrations (of the order of 50 µg per ml) were required to inhibit the growth of *Mycobacterium tuberculosis* On the other hand in vivo, by the mouse corneal method [4] the drug was found to possess some retarding effect on the development of lesions, the order of effectiveness being that of P A S There was no effect on a P A S-resistant strain

Since it is very important to try to find a more palatable substitute for P A S further experimental work is in progress and the question of a clinical trial is under consideration

FULMINATING BERIBERI

SIR,—Dr Baron and Mr Oliver write (Feb 15) "admittedly aneurine alone can be successful but deficiency of one vitamin alone is rare" I submit that deficiency of aneurine alone, or rather the need in some individuals for large daily doses of aneurine, is less rare than is generally believed Some authorities state that, except in the initial treatment of acute cardiac beriberi, there is no justification for the administration of single doses in excess of 10 mg [5] [6]

There are reports of isolated instances of the successful use of aneurine in such varying conditions as herpes zoster,[7] varicose ulcers,[8] vesicular atony,[9] and, for its analgesic effect, in the first and second stages of labour [10] I suggest that, if larger doses of aneurine had been used in the past, many more reports of its efficacy in a variety of conditions could have appeared

Three cases are known to me which indicate, not so much a deficiency of the vitamin, as a need for additional daily intake of relatively large amounts

A white man, aged 42, otherwise healthy, had had recurrent attacks of herpes simplex since childhood, these were at times debilitating In 1948 he was given aneurine hydrochloride 200 mg daily by mouth, since that time, except for short periods when the medication was neglected, he has had no recurrences of herpes simplex

A white woman, aged 40, had for several years been taking daily doses of up to gr 15 of cascara sagrada for constipation In 1954 she was given aneurine hydrochloride, and since that time has been taking daily oral doses of 200–400 mg, with complete relief from all symptoms of constipation

A white girl, aged 14, had had nocturnal enuresis since infancy She had been examined, at different times, by a general practitioner, a pædiatrician, a urologist, and a psychiatrist, in each case except for the nocturnal enuresis the child appeared to be normal and healthy No cause could be found for the condition and no medication helped until, in November, 1957, she started taking aneurine hydrochloride Initially she was given 25 mg daily by mouth with partial success, the dose was increased to 400 mg daily by Dec 7, 1957, and maintained at that level since The nocturnal enuresis ceased on Dec 8, and has recurred only once since, when the aneurine was omitted

There is, I submit, often a case for giving aneurine, providing the dosage is high enough Most of the difficulties reported with administration of aneurine, and there have been several,[6] [11] have been during parenteral use, I have not come across a single adverse reaction to oral administration

A thorough study of the need for aneurine in man and its utilisation could be most rewarding

Saint John, New Brunswick JOHN E WASSON

THE LAW AND STERILISATION

SIR,—Your review (March 22) of my book, *The Sanctity of Life and the Criminal Law*, leaves room for misunderstanding which I should be glad of the opportunity to remove You say "Dr Williams' apparent advocacy of compulsory sterilisation might be harmfully taken much further by others than he himself intended" In fact I am not in favour of compulsory sterilisation I merely urged the implementation of the Brock report, which was concerned with voluntary sterilisation

My discussion of the committee's report proceeded as follows (p 108)

> "The committee, which gave attention to this problem of consent, expressed itself as convinced that when the higher-grade defectives ask for sterilisation, perhaps to assist themselves in obtaining a discharge, or in some cases to be allowed to marry, they understand what they ask for 'The essence of a voluntary system,' said the committee, '*is that* those who object should be free to do so What matters is that there should be no compulsion So long as there is no unfair pressure and no patient *is* forced or bribed to consent, it seems to us mere casuistry to discuss how far the patient full appreciates all the implications of consent'"

The terrible abuses of the Nazis did great harm to the cause of eugenics, but in my study of the working of the American sterilisation laws I think I showed that their results gave ground for confidence To quote my own words again

> "The American experience is of great interest because it shows how remote from reality in a democratic community is the fear—frequently voiced by Americans themselves—that voluntary sterilization may be the 'thin end of the wedge', leading to a large-scale violation of human rights as happened in Nazi Germany In fact, the American experience is the precise opposite—starting with compulsory sterilization, administrative practice has come to put the operation on a voluntary footing"

And again "No one with experience of sterilisation laws now advocates a compulsory system"

MEDICAL SUPERVISION IN TREATMENT OF OBESITY

SIR,—Obesity is now one of the leading causes of death and disability,[1] and its cost to the nation is incalculable Yet it has been proved beyond doubt that sufficient reduction of calorie intake will produce loss of weight in every case

A survey of 500 consecutive patients seen in the medical outpatient department at St James' Hospital, Balham showed that about a third had conditions either produced or exacerbated by obesity—defined as a weight more than 20% above normal weight for height and age according to the standard tables of Kemsley [2]

Before July, 1956, some of these patients were given dietetic instruction and referred back to their own doctors; others, usually those with more serious medical conditions, were treated for a time in the outpatient department, often seeing a different doctor each time, and when weight-loss seemed satisfactory, they were discharged with instructions to continue on their own

A follow-up of 133 of these patients after at least six months showed that weight-loss had been satisfactory (i e, more than 30% of excess weight had been lost) in only 6% 63% had failed to lose more than 7 lb, and 26% had actually gained weight

During the past eighteen months an attempt has been made to treat obesity more vigorously No patient has been discharged until the weight has been normal for at least six months I saw all the patients myself, most of them at every attendance, time has been spent in discovering the background of each patient's obesity and the special difficulties in treating it.

Treatment was dietary whenever possible, with the object of re-educating the patient's appetite rather than achieving a rapid weight-loss The principles of low-carbohydrate diet were explained Drugs, including dexamphetamine sulphate, 'Preludin', 'Drinamyl', and thyroid extract were used when they were considered necessary Patients were seen initially at intervals of two, three, or four weeks, and when weight-loss was satisfactory the intervals between appointments were gradually extended to three or six months

SUCCESS IN THE TREATMENT OF OBESITY

—	Old methods (133 patients)	New methods* (120 patients)
Satisfactory weight-loss (more than 30% of excess weight lost)	6%	67%
Slight weight-loss (more than 7 lb but less than 30% excess weight)	31%	27%
Unsatisfactory weight-loss (less than 7 lb or gain in weight)	63%	6%
Reached and maintained normal weight	4%	25%*
Gained weight during treatment	26%	1 7%

* Ultimate figures will probably be higher since most of these patients are still under treatment.

Of 120 patients who have attended for more than three months, 67% have achieved satisfactory weight-loss and 25% have already reached and maintained normal weight. Only 6% have failed to lose at least 7 lb, and of these 1 7% have gained weight Results in the previous "failures" were as good as in the new cases

The results in the two groups are compared in the accompanying table, and indicate that the treatment of obesity without strict medical supervision is unsatisfactory, whereas close medical supervision results in successful weight-loss in a high proportion of cases The improvement in health in these patients, many of whom have been semi-invalids for years, is enormous Many have previously cost the hospital many hundreds of pounds, but their health is now so much improved that they no longer require frequent attendances and investigations in various departments of the hospital It seems likely that if every obese patient seen either in hospital or in general practice was treated along these simple lines, the health of the nation would be improved and the cost of the National Health Service reduced

I thank Dr Alexander Kahan, consultant physician at St. James' Hospital, Balham, for permission to study his patients, and for his helpful advice and criticism

St. James' Hospital,
London, S W 12.

ALLERGY TO COW'S MILK

SIR,—As the leaders commercially of the present trend towards evaporated milk as a standard infant food in Great Britain, we must comment on the final paragraph of your annotation of Feb 8 in which you suggest that the dried milks used in this country are less liable than evaporated milk to give rise to allergy

While we assess—from constant contact with doctors—that milk allergy is fairly frequent, we have on record, from the same group of professional contacts, an extremely dramatic improvement in, particularly, eczematous conditions when the children were changed from dried-milk foods to evaporated milk

This is supported by Sturrock [1] in a study of four groups of infants fed on breast milk (control), cow's milk, dried milk, and evaporated milk Breast milk and evaporated milk showed up to advantage 60% in both these groups had a clear skin at each of the six weekly observations made. Cow's milk and National dried milk showed up unfavourably on the whole and, from clinical experience generally, it was not surprising to find the relatively high incidence of urticaria in babies taking these milks

Ratner and Gruehl [2] said that evaporated, freshly boiled, and acidified evaporated milk, fed by mouth, was notably less sensitising They also refer to feeding experiments with various forms of milk undertaken to determine whether there was a further diminution of sensitisation when heated milks were fed. Raw skimmed milk, 'Smaco' 303 (special hypo-allergenic preparation), and dried milks sensitised more than 50% of the animals, while milk freshly boiled for four hours was much less liable to produce sensitisation, and so was evaporated milk.

Ratner [3] had this to say of dried milks

> "The antigenic changes that result from various drying processes applied to milks were studied, and it was found that the rapid drying—which is almost instantaneous—did not influence or diminish the antigenic powers of the milk proteins "

We believe that the production of special hypoallergenic milk powders both in this country and the United States indicates the awareness of dried-milk manufacturers that normal milk products have shortcomings for some milk-sensitive infants

Evaporated milks, under exhaustive research in the United States, have clear hypoallergenic advantage over other cow's milk preparations (including dried milks), with the possible exception of fresh cow's milk boiled for four hours

We note with interest your reference to the desirability of a British study of the incidence of milk-protein allergy, and we hope that such research will in fact be undertaken

Obituary

ALEXANDER JAMES HUTCHISON RUSSELL

Kt, C B E, M A, M D, LL D St And, D T M, D P H

Sir Alexander Russell, whose death on March 22 we announced last week, had a distinguished career in India, where he was public health commissioner from 1933 until he entered his busy retirement in 1939

He was born in 1882, the son of Walter Nicoll Russell, a schoolmaster in Glen Devon, and he was educated at Dollar Academy and the University of St Andrews, where he graduated M B in 1906 The following year he joined the Indian Medical Service After a period of military duty he was appointed for civil employment to the Madras Presidency and in 1913 he became medical officer of health of Madras city Before long he realised that his chief interest lay in preventive medicine, and in 1914 he was appointed professor of hygiene and bacteriology at Madras Medical College After five years he turned to pathology and he held that chair for several years

In 1921 Russell re-entered the public service as provincial director of public health He was selected as medical assessor to the Royal Commission on Labour in India, which was set up in 1930, and in 1931 he was a delegate to the Office International d'Hygiène in Paris While he was in Madras he reorganised the public-health department and trained a body of keen and devoted young medical officers, inspiring them with his own high ideals of service With his appointment in 1933 as deputy director-general of the I M S Russell reached the most exacting phase of his career In the same year he was made public health commissioner with the Government of India, and held this post till 1939 His reports were first-rate examples of his power of shrewd analysis and terse, vigorous expression, and his editions of *McNally's Sanitary Handbook of India* (1916 and 1923) were widely read

Of Russell's work in India E W C B writes

Long before he became public health commissioner he had shown, during his career in Madras, high administrative ability, and though he succeeded to the appointment during a period of financial stringency his drive and enthusiasm overcame many difficulties As in Madras his tenure was one of steady progress towards the building up of a sound public-health conscience in the Government of India He was an expert in statistics, having held a fellowship under the Rockefeller Foundation and studied the subject in the United States As a man Russell was a sturdy, lovable Scot, intensely loyal to all his officers, and to his chiefs in the Medical Service At headquarters in Delhi and Simla his administrative qualities found full scope and his opinion, never intolerant, was invaluable India owes a great debt to Russell and the I M S salutes one of their worthiest officers

Soon after Russell returned to this country in 1939 war broke out He began his nominal retirement by helping the group officer of the Emergency Medical Service at Oxford, and during the winter of 1939–40 he lectured on hygiene to the senior medical students In June, 1940, he joined the Department of Health for Scotland as a temporary medical officer and a few months later was appointed to the temporary post of deputy chief medical officer in the same department, with special charge of the national campaign against diphtheria, and he held this post till 1945 During 1944 his services were asked for by the Colonial Office as chairman of a committee to report on the medical and health services of Trinidad and Tobago, and in 1945 he visited Austria as a member of a medical mission on epidemic control

J M M writes

In this active third phase of his career he added distinction to his wide reputation, by devoted and unselfish service He was admired and loved for his delightful personality, he brightened all social relationships with his pawky humour, and shared in all the activities of his colleagues He had been in his regimental polo team in the early days, and in his later years he played a steady game of golf and was a member of the Royal and Ancient Even in his final retirement at Bridge-of-Allan he took his place on many local committees, while he and his wife gave hospitality in generous measure It was a happy time so close to the hills that watch over Glen Devon

RALPH EWART JONES

B Sc Birm, M R C S, D P H

Dr Ewart Jones, director of the regional public health laboratory at Coventry, died on Feb 8 at the age of 53

He was born at Sutton Coldfield and educated in Birmingham at King Edward's School and at the medical school After qualifying in 1927 he held a house-appointment at Hallam Hospital, West Bromwich, and was assistant clinical pathologist at Birmingham General Hospital before he became assistant to Prof J F D Shrewsbury in the department of bacteriology of Birmingham University Later he was appointed senior lecturer in the department During the late war he was seconded to the Emergency Public Health Laboratory Service under the Medical Research Council, and he was in charge of a laboratory at Wrekin College, Wellington, which was ultimately transferred to Hereford In 1948 he was appointed to his present post and for the past two years he had also been honorary lecturer in bacteriology in the University of Birmingham He leaves a widow

P M P writes

I became Ewart Jones' assistant at a time when he had every appearance of robust health, and came to value him highly as a director, a bacteriologist, and a friend He was conscientious and painstaking, a man of charming personality who gave and expected the best at all times The welcome he gave in his home was without reservation, and behind his urbanity was always a quiet humour which was a delight to those who knew him That he possessed the sterner qualities of supreme courage and impassive fortitude became evident when illness overcame him, for his demeanour remained calm and unflinching, and he did not alter his way of life

Parliament

Consultants

Mr KENNETH ROBINSON asked the Minister of Health the number of consultants, excluding psychiatrists, in the employ of each regional board and the number of staffed beds, excluding mental and mental-deficiency beds, in and the population served by each region —Mr DEREK WALKER-SMITH replied The information is as follows

Regional hospital board	Number of consultants, whole-time and part time (excluding psychiatrists) at 31 12 56	Number of staffed beds (excluding beds allocated to mental illness and mental deficiency) at 31 12 56	Estimated population of region in thousands at 30 6 56
Newcastle	353	15,338	2914
Leeds	299	17,753	3066

Notes and News

ANOTHER "UNIVERSAL DIAGNOSTIC TEST"?

LAST month there was quite a flutter in some American newspapers about the announcement of a "new test for the early diagnosis of disease" "Blood Cell Study Seen Quick Way to Diagnose All Disease Medical Break-Through?" was the headline in the *Baltimore News-Post* for March 19 Prof Winston H Price, of Johns Hopkins University School of Public Health, who is in charge of the team working on these tests, and had described his work at a closed meeting, refused to be drawn by reporters, but on March 23 the *New York Times* gave a sober and informative account of this work

Apparently Dr Price and his colleagues have been working on the serum-mucoproteins These substances have been studied for many years, as long ago as 1940 Rimington described their characteristic properties[1], and ten years ago Winzler et al[2] showed that the serum-mucoprotein was a mixture of three components It has long been known that the serum-mucoproteins are increased in rheumatoid arthritis and in other diseases too, thus Kelley et al,[3] for example, found that results from estimating the serum-mucoproteins roughly paralleled changes in the erythrocyte-sedimentation rate, except that in chronic heart-disease the mucoprotein estimation was the more reliable The changes in serum-mucoproteins have been accepted as one of the non-specific manifestations of diseases involving tissue destruction—like the erythrocyte-sedimentation rate and C-reactive protein What Dr Price and his colleagues are reported to have found is that the relation to each other of the three serum-mucoprotein components differs in different diseases, and that completely abnormal mucoproteins appear in some conditions Thus, according to the *New York Times* report, in nephrosis and nephritis only one of the three normal mucoproteins was present, the other two being missing altogether, and in mental diseases all the serum-mucoproteins were abnormal In cancer at four sites—prostate, kidney, gastrointestinal tract, and lung—four abnormal mucoproteins were present, the proportions of these four abnormal components was the same for tumours at the first three sites but differed for "lung" cancer In acute diseases, such as rheumatic fever, the serum-mucoprotein values were high and remained raised after clinical recovery

An announcement from Johns Hopkins, quoted by the *New York Times*, is properly cautious "It cannot be too strongly emphasized", it states, "that the number of cases in each disease that have been analyzed is small, and that much more data will have to be accumulated before the true significance of these patterns (of the blood-serum fraction) can be determined." But it seems from this report that Prof Winston Price has extended the study of serum-mucoproteins to a point where he hopes that the results will give more specific information than has previously been obtainable from tests of this type All physicians are familiar with the patient who has vague symptoms and is found to have a raised erythrocyte-sedimentation rate, such a finding inevitably leads to further and often fruitless blood-counts, X-rays, and studies of blood chemistry The serum-mucoprotein fractionation may indicate more specifically where to look, and whether to seek infection or malignancy From the preliminary results quoted, the pointer to the site of a lesion is hardly specific, but the indication about the type of lesion may be more reliable Work on the early detection of malignancy by studying changes in serum-proteins has been going on for a long time Perhaps the Johns Hopkins group have really made the method work There is no denying that such a test would be very useful

INTERNATIONAL CHILDREN'S CENTRE

AT the opening ceremony in 1950, Prof Robert Debre said "Conceived as an institution for information, instruction, mutual aid and cooperation, the International Children's Centre hopes to contribute to better conditions for all the children of the world" Last year the activities of the centre included two seminars (on primary tuberculosis and pertussis), research on tuberculosis vaccination, the prevention of rheumatic fever, and the growth and development of children, and eight courses of instruction on such topics as reablement of crippled children, school health, child welfare (including a five-month course for African midwives at Dakar), and the care of premature infants This and other work is set out in the annual report.[1]

HEALTH SERVICES FOR THE ARAB REFUGEES

ONE of the most tragic results of the 1948 war in Palestine has been the plight of the several hundred thousand Arabs who then left their homes to take refuge in neighbouring Jordan, Lebanon, Syria, and the Gaza Strip Today most of these people still live in the same places where in 1948 they arrived hungry and destitute awaiting relief from the local Arab Governments

As the weeks following their exodus stretched into months, and they found that they could not return to their homes, it became apparent that more organised relief was essential if a major catastrophe was to be avoided The risk of epidemics was already serious when in 1949 the United Nations Relief for Palestine Refugees was set up to carry out relief with the aid of the international committee of the Red Cross, the League of the Red Cross Societies, and the American Friends Service Committee

The small health teams which were organised a decade ago by a W H O specialist to meet the emergency have since developed into an efficient health force serving nearly a million refugees now living in camps, towns, and villages scattered over 100,000 square miles in four different countries The United Nations Relief and Works Agency which took over relief activities in 1950 is now spending at the rate of $5 million a year on its health programme alone. Its 3500 employees include 120 doctors and dentists and over 450 nurses, nursing auxiliaries, and midwives Its technical direction is the responsibility of the World Health Organisation There are 92 clinics (attracting 6 million visits a year) and 2000 hospital beds in U N R W A and other hospitals, but preventive work is given priority it includes attention to water-supplies and disposal of sewage and waste, an anti-malaria campaign (with swamp drainage and insecticide spraying), which has led to a fall in the proportion of malaria patients seen in the clinics in East Jordan from 18 5% in 1953 to 0 66% last December, mass inoculations (including, last year, 254,000 against typhoid and 497,000 against smallpox), supplementary feeding of the sick, of pregnant and nursing women, and of children, and health education, particularly in hygiene and child care At the maternal health centres, besides receiving such instruction, pregnant women (100,000 consultations last year) are cared for, including tests—and, where necessary, treatment—for syphilis, the provision of a simple layette, and supervision of the infants up to the age of two years

By these means serious epidemics have been avoided, and in some ways, the health of the refugees has been improved, but their housing is far from satisfactory and their rations are the minimum needed for subsistence The work of the health programme must continue, and so must the contributions of Governments to the funds of the agency

BETHLEM AND MAUDSLEY HOSPITAL REPORT

IN his article of March 15 (p 578) Dr C P Blacker referred to the triennial statistical report of the Bethlem Royal Hospital and the Maudsley Hospital for the years 1952–54, which he has edited The report has now been published (pp 152, 10*s* 6*d*)

CORTICOTROPHIN—A CORRECTION

LAST week we said that corticotrophin preparations may now be prescribed on form E C 10 This is not so

LESS DIAMORPHINE USED

SOME time ago the Economic and Social Council of the United Nations expressed the hope that diamorphine (heroin) would no longer be used[1] In its eighth report[2] the W H O Expert Committee on Addiction-producing Drugs notes " that the relatively small residuum of licit use of diacetylmorphine was tending to be further reduced " The committee believes that this substance " can be replaced by more than one drug with less risk to public health "

University of Dublin

On Thursday, May 1, at 5 P M , at Trinity College, Dublin, Prof A Hagedoorn, of Amsterdam, will give the Montgomery lecture on the gross and minute defects of the germ cells and clinical ophthalmology

Royal College of Physicians of London

On Tuesday and Thursday, April 15 and 17, Dr J St C Elkington will give the Lumleian lectures on cerebral vascular disease in the light of modern techniques

On Tuesday and Thursday, May 13 and 15, Dr Paul Wood will give the Croonian lectures His subject will be the Eisenmenger syndrome, or pulmonary hypertension with reversed central shunt All the lectures will be given at the college, Pall Mall East, S W 1, at 5 P M

St George's Hospital Medical School, London

Postgraduate demonstrations in psychiatry will be held at the School, Hyde Park Corner, S W 1, on alternate Thursdays at 5 P M They are open without fee to doctors and senior medical students The first will be given by Sir Paul Mallinson on April 17

West London Medico-Chirurgical Society

On Wednesday, April 16, at 8 30 P M at the house of the Royal Society of Arts, John Adam Street, W C 2, Sir Gordon Gordon-Taylor will give the Cavendish lecture His subject will be On Tradition

Nutrition and Climatic Stress

The Scottish group of the Nutrition Society is holding a symposium on this subject at the Hannah Dairy Research Institute, Kirkhill, Ayr, on Saturday, April 26 Papers will be read on human and animal nutrition Further particulars may be had from Dr J Davidson, The Rowett Research Institute, Bucksburn, Aberdeenshire

International Congress for Manipulative Therapy

This congress will be held in Baden, Switzerland, from May 1 to 4 The speakers will include Dr J H Cyriax and Dr Alan Stoddard Further particulars may be had from the president, Dr J C Terrier, Badstrasse 64, Baden, Switzerland

N H S Award

The Industrial Court has awarded a 4½% pay increase to more than 1100 technical staff in the National Health Service The staff who will receive the increase will include medical photographers, dark-room technicians, and physics technicians They received their last increase in August and September, 1956 The new rates will be paid from the beginning of March

Laboratory Animals Centre

This centre is holding a symposium on Monday, May 5, at 9 30 A M, at 1, Wimpole Street, London, W 1, on the organisation and administration of an animal division Further particulars may be had from the Laboratory Animals Bureau at the centre's new address at the M R C Laboratories, Woodmansterne Road, Carshalton, Surrey

The high sheriff of Carnarvonshire for 1958-59 is Prof R H Parry, formerly principal medical officer to Bristol City Council

Dr George E Wakerlin has been appointed medical director of the American Heart Association, in succession to Dr Eugene B Ferris, who died last September Dr Wakerlin, formerly professor of physiology and pharmacology at the University of Illinois, took up his duties on April 1

Dr Richard Emanuel is to be one of the recipients of an award made by the American Society for Clinical Investigation for work carried out at Vanderbilt University, Nashville, on indicator dilution methods for describing circulatory systems He was given a year's leave from the National Heart Hospital, London, to take part in this investigation

The United Hospitals' Choir is to give a performance of *Belshazzar* by Handel at 7 30 P M on Tuesday, April 22, at St James's and St Peter's Church, Piccadilly, London, W 1 Admission will be by programme (*3s 6d*, *5s*, and *7s 6d*), which may be had from Miss J Magrath, 18, West Side, Clapham Common, S W 4

The photographic department of St Mary's Hospital Medical School, London, W 2, has made 15 films, which may be borrowed free (except for a few shillings for postage and packing) for medical audiences (including nurses) or scientific film societies All are 16 mm A catalogue may be had from the department

The Directory of Child Guidance Services in England and England and Wales, published by the National Association for Mental Health, lists alphabetically under counties the child-guidance clinics and gives for each the address, names of staff, and days of attendance. Copies (*5s*) may be had from the Association, 39, Queen Anne Street, London, W 1

To any doctor who writes for it the National *Marriage* Guidance Council will send a free copy of *Sex in Marriage*, to which we referred on March 1 (p 487) Requests should go to Mrs Angela Reed, publications officer, National *Marriage* Guidance Council, 78, Duke Street, London, W 1, who will also supply order forms which can be given to patients wishing to order their own copies direct from the Council

Diary of the Week

APRIL 6 TO 12

Tuesday, 8th

ROYAL COLLEGE OF SURGEONS OF ENGLAND, Lincoln s Inn Fields, W C 2
5 15 P M Mr E G Muir Carcinoma of the Rectum and Anterior Resection
6 30 P M Mr T Holmes Sellors Diagnosis and Treatment of Atrial and Septal Defects
ROYAL SOCIETY OF MEDICINE, 1, Wimpole Street, W 1
8 P M *Psychiatry* Dr Bernard Zeitlyn Postoperative Psychoses

Wednesday, 9th

THE THYROID NODULE*

SELWYN TAYLOR†
M Ch Oxon, F.R.C.S
SURGEON, KING'S COLLEGE HOSPITAL; LECTURER IN SURGERY, POSTGRADUATE MEDICAL SCHOOL OF LONDON

IT is almost twenty-five years since, as a physiology student, I read Harrington's (1933) textbook on the thyroid gland, yet on rereading my notes I find little that needs altering after all the intensive research work lavished on this single endocrine gland in the succeeding quarter of a century There is much, however, to add to this earlier account, and here I want to weave together something old and something new to try and explain why nodules appear in the thyroid gland, their natural history, and how we may hope to diagnose them correctly and treat them rationally Those of us who still like to be called general surgeons are continually confronted by the patient who harbours a readily palpable thyroid nodule, and our first question must surely be is this goitre simple, toxic, or malignant? I have a particular interest in simple or non-toxic ones, certainly they are the most common

The Simple Nodule

Lack of Iodine

Simple goitre is primarily due to failure of the thyroid gland to obtain sufficient iodine to maintain its normal structure and function In most parts of the world a deficiency of iodine is the commonest cause of a nodule in the thyroid gland of a young person and of multiple nodules in older people The ancients used burnt sponge and seaweed to treat goitre, which was splendid empiricism because iodine was not discovered until 1811 by the Frenchman Courtois (1813) At that time our fleet was blockading the French coast, and Napoleon could not import the nitrates he required to make gunpowder His backroom boys therefore devised other means of obtaining nitrates, they used a process involving, at one stage, the admixture of seaweed ash with sulphuric acid in metal vats It seems that Courtois one day had perhaps added stronger acid than usual, because beautiful violet vapours were seen to arise which proved to be a new element, iodine Thus Napoleon's gunpowder gave us iodine, just as nuclear fission has given us radioactive iodine

Soon after Courtois' discovery of the new element Sir Humphry Davy (1814) confirmed the presence of iodine in seaweed and Fyfe (1819) in sponges, and as early as 1816 Dr William Prout was prescribing potassium iodide for goitre Some remarkable micro-assays by Chatin (1850–76) put the whole subject on a sound scientific foundation, from which it was unfortunately toppled by some unsatisfactory attempts at preventing goitre with iodine in the French provinces Thus the way was paved for the infective theory of goitre to gain the ascendant, probably helped by the great interest taken at that time in the work of Pasteur and Koch However, although this temporarily distracted attention from a low intake of iodine as the cause of thyroid enlargement, it encouraged investigations into those other goitrogenic substances whose presence becomes important in the iodine-deficient areas of the world In such areas the daily intake of iodine is less than 100 µg, the quantity determined by Curtis and Fertman (1950) as necessary for normal function of the thyroid gland in an adult

Evolution of Simple Goitre

The natural history of thyroid enlargement in an area of endemic goitre has been carefully documented in the past (Olesen 1924, 1926, 1929, Olesen and Taylor 1926, 1927), especially by public-health workers In an area of average severity the thyroid appears moderately enlarged in early childhood This type of enlargement was called by Murray et al (1948) the Rossetti neck At the age of 5 years, about a quarter of the boys and a third of the girls may be so affected, and by puberty the incidence is usually at its highest

Puberty goitre has been regarded as a physiological (McCarrison 1917) rather than a pathological response to lack of iodine because it reflects the great demands made on the gland at this period and may be entirely reversible I have, however, seen young adults with thyroid nodules who had only spent the first 5–10 years of their lives in an endemic goitre area and had then moved to a district where the intake of iodine was adequate

After puberty it is usual for the enlarged thyroid gland to diminish in the male but to persist in the female, in whom it usually enlarges a little before each menstrual period and considerably during pregnancy At the age of 30 nodules have often appeared, and the real problem there is when and why the diffuse hyperplasia of puberty becomes nodular in the third decade and later

Autoradiographic Studies

In an attempt to gain insight into the processes taking place in nodular goitre we have prepared in the laboratory autoradiographs from well over a hundred patients operated on for simple goitre

Autoradiography, a technique to which I was first introduced by Brown Dobyns, is ideally suited to the study of goitre because it gives a physiological rather than an anatomical picture of what is going on when the tissues are removed It consists in exposing a slice of the thyroid gland to a piece of photographic film, which becomes black where the tissues contain radioactive material Thus it makes possible a comparison of the histology of any area with its capacity to concentrate and bind iodine to protein—in other words, to manufacture thyroid hormone

The patients investigated were representative of most types of simple goitre, being drawn from those with sporadic goitre in London and others from endemic areas in Southern Ireland who had come to work in London

Each patient was admitted to hospital and, after a thorough history had been obtained, including details of dietary habits, district where born and bred, and any family incidence of goitre, was given a tracer dose of radioactive iodine The urine was collected for forty-eight hours and the overall activity of the gland determined by the method of Fraser et al (1953) Partial thyroidectomy was done, and slices of tissue were cut through whole lobes to get a good overall picture The tissue was fixed and cut exactly as for ordinary histology, and these giant slices were then put in contact with pieces of X-ray film, which were developed at one, two, and eight days and then compared with the histological sections

---

* From a lecture delivered to the section of surgery of the Manchester Medical Society on Dec 10, 1957

† In receipt of a grant from the British Empire Cancer Campaign some of the work described here was done with a grant from the Medical Research Council

Examination of these autoradiographs at once revealed many interesting features In diffuse simple goitre the blackening showed a fairly uniform peppering throughout the gland, but in older patients the greater part of the thyroid gland appeared to concentrate no radioactive iodine at all, there being only small discrete foci of blackening Blackening only takes place in areas where there is iodine-containing colloid Colloid does not necessarily contain iodine The features which distinguished those follicles capable of doing this from the others was that the former were small in diameter, with tall cells Rawson and Starr (1938) showed that increased height of the follicle cells indicated increased stimulation of the thyroid gland In addition these small active follicles were grouped together in a characteristic way The diameters of 100 follicles in active and non-active areas were measured in two axes at right-angles to each other The diameters of the active follicles were not only about a third of those of the inactive ones but also were much more uniform in size (Taylor 1952)

When autoradiographs of the whole series of goitres were examined in conjunction with the histological preparations and case-histories of the patients, it appeared possible to reconstruct the natural history of the disease (Taylor 1953) This evolution of nodular goitre I have divided arbitrarily into five stages, although appreciating that other workers might interpret the results differently

Stage I is diffuse enlargement of the thyroid gland, which shows increased vascularity, a large uptake of radioiodine, and uniform blackening of the autoradiograph This is the typical puberty goitre but may persist for years

Stage II comprises all those thyroid glands which show discrete focal areas of hyperplasia with corresponding blackening of the autoradiograph There are very few patients in whom all the functioning thyroid tissue is concentrated in a single area, Rawson when shown autoradiographs of this condition, immediately described it very aptly as a toxic nodule in a non-toxic gland It is fashionable at present to call this a hot nodule in a cold gland, but it must not be forgotten that the patient presents the picture of normal thyroid (euthyroid) function

Stage III—Before the next stage in this evolution is described, it is necessary to appreciate the internal architecture of the thyroid gland The building-blocks from which the gland is constructed are follicles, each being a spherical structure made up of a single layer of cells covered by a basement membrane and a rich network of blood-vessels Johnson (1953, 1954), by perfusing excised glands with warm saline solution, has split up the connective-tissue planes to show that each 20–40 follicles are bound lightly together to form a lobule, each lobule being supplied by a single artery This important lobular or " unit " construction was known a century ago but in recent years was doubted, probably because of methods of wax-model reconstruction (Rienhoff 1930) from serial sections which hinted at a branching structure

It appears from our autoradiographs that these lobules work as single units and become increasingly more hyperplastic and vascular This stage is typified by disruption with hæmorrhage, which is followed by necrosis, and on the autoradiograph only a rind of active tissue is seen

Stage IV is the end-result of stage III The nodule undergoes resolution in one of two ways either a large lake of colloid fills it and this is found to be free of iodine, or a mass of new follicles grows to supersede it, and again their colloid does not take up radioiodine

Stage V is the multinodular or pudding-stone goitre, brought about by the continued repetition of the process described above, with the result that most of the nodules are inactive and incapable of metabolising iodine, but among them will be found a few active foci which are currently supplying the body's hormone requirements

Experimental Goitre

Nature has made some vast experiments in the production of goitre in various parts of the world, and this has stimulated research, such as McCarrison's in the foothills of the Himalayas fifty years ago and Stanbury's (1954) in Argentina Both McCarrison and Stanbury noted that, with an improved standard of living, more articles of diet were imported into the district and, containing iodine, lessened the incidence of goitre Thus, in the endemic areas of the world, the poorer the individual the bigger is his goitre

These great endemics can be imitated in miniature in the laboratory by giving rats a low-iodine diet, where the decreased output of thyroxine by the thyroid gland leads to increased activity of the basophil cells of the anterior lobe of the pituitary gland, with a proportionately increased rate of secretion of thyroid-stimulating hormone (T S H) This enhanced activity of the pituitary gland explains the postmortem observation made by Nièpce (1851) that cretins have large pituitary glands

In my own laboratory we have maintained rats for two years on a low-iodine diet, killing them at intervals and attempting to reproduce the stages in the development of nodular goitre seen in man (Taylor and Poulson 1956) Unfortunately we found that the thyroid gland of rats behaved like a single human thyroid lobule, and hyperplasia was uniform and not focal, we obtained nodules, but they were not hyperplastic However, it led to an investigation of the individual items in the diet we found that calcium carbonate, which is a usual constituent of rat diets, is very goitrogenic in young animals on a low iodine regime (Taylor 1954) This observation correlates well with the fact that in the low-iodine areas of the world, where there is much chalk or limestone, goitre is more common—e g , Derbyshire How salutary it is to read the work of Boussingault (1831), who mapped out the goitrous areas of Colombia and related them to the presence of limestone

Since the nodules in goitre appear to be related to increased secretion of T S H , we have been taking excised thyroid glands straight from operating-theatre to laboratory Tissue slices of nodular and non-nodular tissue have been studied in a Warburg apparatus, but no technique that we have evolved has shown a difference in the responsiveness of the two kinds of tissue to T S H (Taylor and Moffitt 1957) An interesting study by Pitt Rivers et al (1957), using chromatography on excised nodules, has disclosed a larger proportion of the precursors of thyroxine, suggesting that the metabolism of iodine in some of these active areas is abnormal

Treatment

The foregoing account makes it possible to be rational in the treatment of simple nodular goitre Prevention being better than cure, an adequate daily intake of iodine is the most important single factor and one which can be readily provided by iodising all domestic salt Puberty goitre and diffuse enlargement of the thyroid gland calls for either gr 3 of desiccated thyroid or sodium *l*-thyroxine 0 3 mg by mouth daily Claims have been made that triiodothyronine 90 0 µg daily is more effective, but in our hands its only merit has been swiftness of effect (When hæmorrhage has taken place into a nodule, the blood-serum should be aspirated through a wide-bore needle, usually nothing further is required) Finally there is thyroidectomy, which is usually indicated for cosmetic reasons, pressure effects, or suspected malignancy It is useless to enucleate single nodules, partial resection of both lobes and the isthmus is necessary When only one lobe is removed, often the patient returns in about five years with enlargement of the opposite lobe.

Since thyroid nodules appear to be due to compensatory hyperplasia, removal of thyroid tissue would deprive the patient even further of an already depleted supply of thyroxine It is true that nature compensates for this remarkably well, but a careful follow-up of patients after thyroidectomy for simple goitre usually shows a brisk increase in weight and fatiguability—a condition readily treated with small doses of thyroid, which may often be gradually reduced after a year or two The patient with a solitary hyperfunctioning nodule presents an extreme example of this, often becoming overtly hypothyroid after operation and, if uncorrected, taking at least three months to regain the euthyroid state The value of thyroid medication in the postoperative period has not been emphasised sufficiently in the past

The Toxic Nodule

Hyperthyroidism due to a solitary toxic nodule is rare, Plummer (1928), of the Mayo Clinic, first drew attention to it It is a condition comparable to that described in stage II, the "toxic nodule in a non-toxic gland", but in this case the mass of functioning tissue is so great that the patient is toxic. Hæmorrhage is usual in this type of nodule, and often the result is spontaneous cure of the hyperthyroidism Most clinicians must have seen the hyperthyroid patient who spontaneously lost all her symptoms I would go so far as to say that this is a self-limiting form of the disease

The toxic nodule is the only one which it is completely justifiable to enucleate, the remainder of the gland being left intact However, the remainder of the gland is atrophic, and its activity is suppressed by the secretion of the toxic nodule Therefore after operation the patient rapidly becomes hypothyroid and may feel acutely depressed Thyroid medication should be started in the immediate postoperative period and gradually diminished in the succeeding twelve months

The Malignant Nodule

The difficulty of deciding when a thyroid nodule is malignant has led to a spate of articles on this subject in recent years, indeed the incidence of malignancy in excised thyroid nodules has been reported at levels varying from 0 to 25% by different workers Crile (1950) was the first to point out that such figures merely reflect the habits of the surgeon, the cancer-rate depending directly on which patients he chooses for operation Certainly this greater alertness to the possibility of malignancy in the thyroid nodule must have encouraged many pathologists to take more blocks of tissue and to cut more sections

Ætiology

Since increased secretion of T.S.H can lead to focal hyperplasia in the thyroid gland, it seems possible that a continuation of the process might play an important part in producing malignancy If this is true, thyroid cancer should be commoner in areas of endemic goitre, and evidence has been marshalled in support of this by Doniach (1956) Switzerland, an endemic goitre area with a population a tenth of that of this country, has a death-rate from thyroid cancer almost identical with ours Furthermore the introduction of iodised salt in Switzerland is beginning to cause a decline in this incidence (Wynder 1952)

A malignant nodule in the thyroid gland has usually a papillary or follicular pattern Papillary carcinomas tend to occur in the younger patients, are non-encapsulated, grow relatively slowly, and spread typically by the lymphatics Follicular carcinomas have capsules which enable them to be shelled out from the gland, and their metastases are commonly blood-borne to bones and lungs Anaplastic carcinoma need not concern us here, because it does not usually present as a nodule

Diagnosis

The correct diagnosis of malignancy in a thyroid nodule is difficult, but the patient's complaint that all is not well in the neck should not be lightly dismissed Hardness, fixity, involvement of other structures, especially the recurrent nerve, all point to malignancy, as does involvement of lymph-nodes Radioiodine has some diagnostic value here because malignant tissue does not usually take it up in the presence of normal thyroid tissue, and thus a careful scan of the patient's neck with a collimated tube, as first described by Dobyns and Lennon (1948) (Taylor and Stewart 1951), may be helpful. If the nodule takes up radioiodine it is unlikely to be malignant Raymond Greene (1957) has reviewed his experience with this technique

Treatment

Whenever a nodule is suspected of harbouring papillary carcinoma, the whole lobe in which it lies should be excised, with careful preservation of the recurrent nerve If any lymph-nodes are involved they should be excised at the same time When follicular carcinoma is discovered it should never be shelled out, but total thyroidectomy should be done, with preservation of some parathyroid tissue The object of total thyroidectomy is twofold, it removes the primary tumour, and, if metastases are already present or develop later, they may be amenable to treatment with radioiodine if the thyroid gland is not there to compete for the isotope

The Prevention of Nodules

When the daily intake of iodine is less than about 100 µg, goitre becomes endemic, more especially where goitrogens, such as calcium, are present in the diet Goitre brings with it a host of complications increased incidence of thyroid cancer, probably increased incidence of hyperthyroidism, all the disability caused by pressure on the trachea, great vessels, and œsophagus, and cretinism (*Bulletin of the World Health Organisation* 1953) Because of these complications New Zealand, Switzerland, the United States, Yugoslavia, and Argentina now iodise their salt. The experience of those countries which have had iodised salt for years is the best proof of its advantages

There are no recorded adverse effects to man of adding 50–100 µg of iodine to the daily diet Although such effects have occasionally been claimed they have, on investigation, been shown to be due to some other factor, usually the addition of pharmacological instead of physiological amounts of iodide Unfortunately iodide added to table salt tends to migrate into the paper or cardboard container, but the use of iodate obviates this If any person wished to use salt without this addition, it could readily be arranged for such salt to be available on demand

The cost to this country annually of not iodising salt must be immense if calculated in terms of demands made on the medical services and loss of working time Why do we not iodise salt? The Medical Research Council recommended it in 1944 and again in 1948 An Order in Council was prepared in 1950 but never completed, the time has now come when we can no longer afford to postpone it

POSTBULBAR DUODENAL ULCERATION

LORNA COOKE
M B Lond, M R C P *
RESEARCH ASSISTANT, GASTROENTEROLOGICAL DEPARTMENT

CHARLES F HUTTON
M R C S, D M R D
ASSISTANT RADIOLOGIST

CENTRAL MIDDLESEX HOSPITAL, LONDON, N W 10

THE diagnosis of postbulbar duodenal ulcer is often missed, and, as a result, patients with a severe and even lethal disability may be regarded as neurotic Even laparotomy may fail to demonstrate the ulcer, confirming the erroneous clinical impression Nevertheless, diagnosis is nearly always possible by radiography if appropriate techniques are used, especially if the clinician and radiologist are fully aware of the pitfalls in the diagnosis and work closely together to avoid them

Before discussing the radiological features, the limits of the duodenal bulb must be defined, so that a clear idea of what constitutes postbulbar territory can be obtained

The first part of the duodenum extends backwards for a short distance from the termination of the pyloric canal In this part of the course it usually runs horizontally, though it may have an upward or even slightly downward inclination Then, at the genu, the duodenum turns vertically downwards in its second part (fig 1)

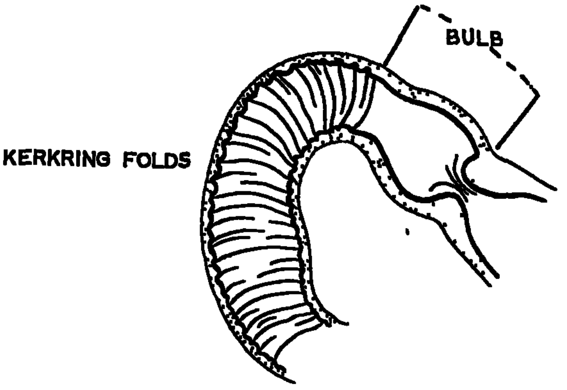

Fig 1—Diagram showing first and second parts of duodenum, with annular folds beginning at distal end of bulb

The bulb forms about two-thirds of the first part of the duodenum and is defined by the mucosal pattern The mucosal folds in the bulb run roughly parallel to its long axis, whereas beyond the bulb the folds become transverse and much coarser in texture The point of this transition marks the junction of bulb and postbulbar area We are here particularly concerned with ulcers in the immediate postbulbar area and genu, where they are most difficult to demonstrate radiologically Any backward inclination of the duodenal bulb tends to align the immediate postbulbar area with the bulb itself or even the pyloric antrum in hypersthenic patients Ulcers do arise in the second and third parts of the duodenum, but they are rarer, and easier to detect

Postbulbar ulceration cannot be excluded until the immediate postbulbar area has been fully displayed In practice, by using a small quantity of barium cream, and taking serial films of the postbulbar region in more or less exaggerated prone and supine positions, one can examine this area effectively without its being obscured by the bulb or pyloric antrum An overfilled stomach may make examination impossible A technique which we have found of value in extremely difficult cases, especially in hypersthenic patients, is to give a small quantity of barium cream, manipulate this into the bulb and second part of the duodenum, and then inflate the stomach through the stomach-tube After suitable rotation of the patient, the postbulbar area can be visualised through the air-inflated pyloric antrum If satisfactory results cannot be obtained in this way with the patient erect, the same technique can be used in the supine or prone positions (figs 2 and 3)

Fig 2—The ulcer is clearly seen through the air-inflated pyloric antrum (patient supine)

The two cardinal radiological features are the demonstration of the crater itself and of any localised stenosis of the duodenum near the ulcer In addition, it may be possible to appreciate local alteration of the mucosal-relief pattern around the ulcer The appearances of the crater are similar to those found in the bulb and require no further description The local stenosis, which is usually present, must be distinguished from incomplete filling of the duodenum or constriction due to normal peristaltic waves

---

* Working on a grant from the Medical Research Council

Differential Diagnosis

A *diverticulum* is the most common source of confusion, but differentiation should be possible because of the smooth rounded outline, the absence of any local stenosis of the duodenum and the normal mucosal folds running into the diverticulum. A careful mucosal study is necessary to show this It may be possible to show the neck of the diverticulum. Finally the site is important, the diverticulum being commonest in the second part of the duodenum and rarest in the immediate postbulbar area

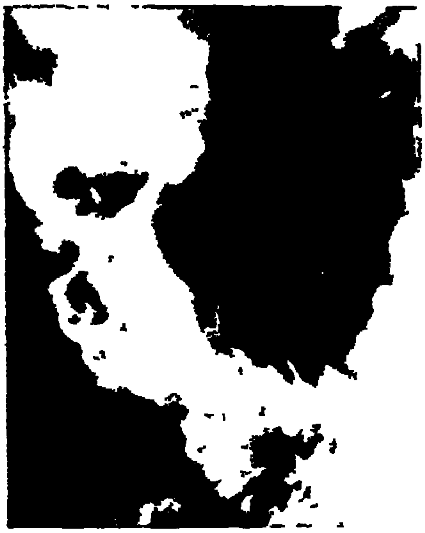

Fig 3.—A fairly large postbulbar ulcer seen through the air-inflated pyloric antrum (patient supine)

An *adhesion band* may constrict the duodenum to produce an area of stenosis, but absence of an ulcer crater and of mucosal changes should serve to avoid confusion

Carcinoma of the pancreas may produce a constriction of the duodenum Other features must be looked for, especially forward displacement of the duodenal loop and widening out of the arc of the duodenum.

Annular pancreas may cause confusion as it constricts the duodenum. Absence of a crater and dilatation above the constriction are the points to look for

Malignant tumours of the duodenum will show irregularity of contour of the growth and possibly irregular translucent areas due to protrusion of growth with the lumen. Also the stenosed area may be more diffuse than is the case with an ulcer

Benign tumours may produce rounded translucent areas with no evidence of stenosis

At the Central Middlesex Hospital, in the year 1949–55, 25 cases of postbulbar duodenal ulceration were diagnosed

Features of Postbulbar Ulcers

Incidence

Increasing awareness of the lesion has improved our standards of diagnosis considerably 10 cases were diagnosed during the five-year period 1949–53, in 9732 barium-meal examinations, but 15 cases during the two years 1954–55, in 4016 examinations

Portis and Jaffe (1938) in a series of 9000 necropsies with 158 duodenal ulcers, found that 5% of the ulcers were beyond the bulb Perry and Shaw (1893), in their large series of necropsies, found 12% of duodenal ulcers beyond the bulb Brule et al (1936) collected 94 cases of ulcers in the second part of the duodenum, of which 84% were ampullary As Preiskel 1952) points out, there is a wide difference between the pathological and the radiological incidence

Age-incidence—Most workers agree on the high average age of patients with postbulbar ulcers Samuel 1952), with whose series ours is most comparable, gives 54 as the average age of his 12 patients with a range of 22 to 82 He attributes this high average age to delay in diagnosis, and we agree. The average age in our series is 51 2 (range 22 to 74) (see table)

Sex-incidence—Our 25 patients comprised 23 men and 2 women, a much higher ratio of men to women than is the case with duodenal ulcer in its more usual site.

Length of History

The average length of history in our series was just over twelve years, with a range of three months to forty years Samuel comments that in 5 of his 12 cases the history was longer than five years, and in 3 longer than twelve years Again we feel that this high figure is due to delay in diagnosis

Clinical Features

These patients' symptoms are generally severe and distressing The most common is pain

Night pain was present in 20 patients It was generally in the back or right scapular region, occasionally in the hypochondrium, often felt only at night. It was difficult to relieve, and more often only transiently relieved by alkalis or food, or occasionally by some unusual drink—e.g , case 1 obtained relief by taking "liver salts'

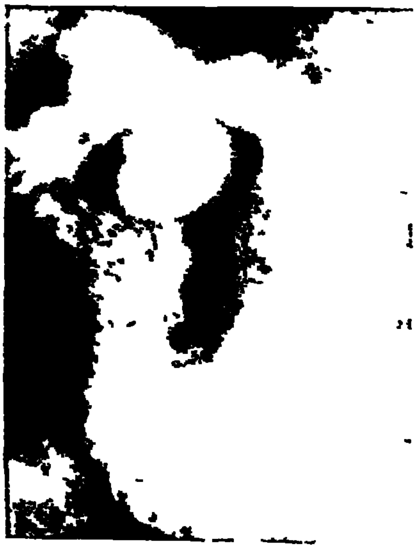

Fig 4—Case 6 the ulcer is just beyond the apex of the bulb There is also stenosis of the lumen of the duodenum in the region of the ulcer (patient prone)

Back pain was the second most common symptom, and was felt anywhere from the right loin to the left scapular region. It was severe and difficult to relieve by food and alkalis It might at first be periodic in character, with several weeks' freedom between attacks, but later became more frequent and might be felt daily

Hæmorrhage —15 of our patients at some time had hæmatemesis or melæna, generally the latter, and bleeding was severe and difficult to control In case 6 (fig 4) and case 13 (fig 5), emergency surgery had to be undertaken

Case 13 —A retired business-man, aged 75, attended the outpatient department in March, 1954, with a twenty-year history of severe attacks of pain and vomiting, especially when he was worried The pain was mostly in the back and kept him awake for a considerable time at night at first it was relieved by food and alkalis but later these were of little use In 1953 he had had a severe attack of melæna, for which he had a blood-transfusion Three barium-meal examinations were all negative, though a clinical diagnosis of duodenal ulcer had been made

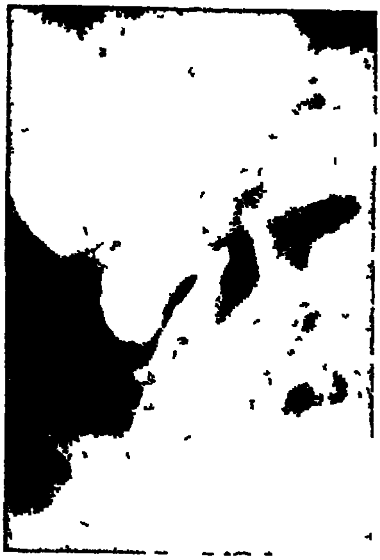

Fig 5—Case 13 the ulcer is in the immediate postbulbar area, with much local stenosis of the duodenum (patient supine)

In March, 1954, a barium-meal examination at the Central Middlesex Hospital showed a large ulcer crater in the second part of the duodenum on the medial side and a deformed duodenal bulb Much duodenal stenosis was evident In view of his age, obesity, and hypertension he was felt to be a poor operative risk and he was followed up as an outpatient He kept reasonably well until October, 1954, when he had a hæmatemesis and was admitted to hospital He settled down quickly and was anxious to return home without further treatment He remained well until December, 1954, when he was again admitted, this time with a severe hæmatemesis and melæna, which continued for some days Despite his poor general health it was felt that operation was essential to save his life The operation was technically very difficult A large ulcer was present in the second part of the duodenum which extended into the bulb The ulcer was nearly 3 in long, and this made closure of the stump very hard The stump broke down within a few days and the patient died some three weeks later

Intermittent duodenal obstruction —5 patients in this series had a history suggesting intermittent upper intestinal obstruction—severe sudden pain and continuous vomiting lasting up to four days, with gradual recovery They were generally quite well between the attacks In all, pyloric stenosis was diagnosed eventually, but 2 were submitted to laparotomy before a correct diagnosis was made These 5 form a subgroup which we feel could be diagnosed clinically All of these cases showed narrowing of the duodenum at the site of ulcer radiologically

Case 4 —A postman, aged 38, attended the Central Middlesex Hospital in 1951 with a slight hæmatemesis and melæna A barium-meal examination showed a large ulcer crater in the second part of the duodenum He remained well for some time, but later developed very severe attacks of vomiting and back pain, which lasted several days and from which he completely recovered with no symptoms in between He had these attacks about six or seven times a year He moved away from this area and attended several other hospitals where he had three negative barium-meal examinations and where neurosis was diagnosed twice and intestinal obstruction once At this time a laparotomy was performed but nothing abnormal was found and no further operation was undertaken

Soon after leaving the hospital he had a further attack and came back to the Central Middlesex Hospital, where a barium meal confirmed the presence of an ulcer and he was admitted for a partial gastrectomy At operation no ulcer was apparent from the external appearances, though the surgeon noted a slight thickening of the head of the pancreas Later an ulcer was felt in the posterior wall of the second part of the duodenum Again difficulty was experienced in closing the stump, and for a few days postoperatively there was a slight leak from the suture line Soon, however, he made full recovery and when seen later said that he "was a new man"

Duodenal obstruction may become persistent if allowed to continue for long without treatment

Case 8 —A retired business-man, aged 62, had an eighteen years' history of pain and intermittent attacks of vomiting, becoming more severe, and nearly continuous for the year before operation At operation a postbulbar duodenal ulcer was found and the second part of the duodenum was very narrowed and fibrosed

Perforation occurred in 1 case (case 6), coincidentally with a severe hæmatemesis The perforation was discovered at emergency operation

Associated Conditions

Diabetes mellitus —2 patients (cases 5 and 23) also have diabetes mellitus, in case 23 this developed at the same time as his symptoms of postbulbar ulcer Case 18 has a low renal threshold for glucose and may have diabetes We are not prepared to draw any conclusions from so small a number of cases

Peptic ulcer —Outside this series of 25 patients we have seen 4 others with a coincidental ulcer in the bulb These have not been included in the series because we felt that the clinical findings might be obscured by an ulcer in the more usual site

Investigations

Barium meal —The table shows that the average number of barium-meal examinations carried out in our patients before a diagnosis was made was 3 (range 1 to 8) Taken in conjunction with the rest of the clinical history, this itself is a suggestive feature

Gastric hydrochloric acid —Test meals were given to 13 of the patients, but did not prove a real aid to diagnosis 9 patients had a high acid curve, 4 had a low curve

Treatment

In postbulbar duodenal ulcers medical treatment is usually unsatisfactory, operation is indicated in most cases, and should be undertaken when the patient is relatively well

7 patients in this series have had gastrointestinal operations

1 had a gastroenterostomy because he was a poor operative risk He has subsequently done very well

6 patients had a Polya partial gastrectomy 2 of these were operated on as emergencies for severe hæmorrhage, 1 also had perforated his postbulbar ulcer Both were severely ill at the time of operation and both died later The remaining 4 have done very well, though 3 had a stormy postoperative period with leakage from the duodenal stump in 2 cases

These operations are often technically difficult The identification of the ulcer may not be easy, and becomes harder the further away from the bulb the ulcer is situated The actual closure of the duodenal stump also presents difficulties, for at operation the ulcer is often found to have extended into the bulb, making proximal closure impossible In such cases, Bancroft's operation may be helpful the pyloric antrum is divided about 1 in proximal to the pylorus, and the mucosa is cored out before closing the stump

Summary

25 cases (23 in men and 2 in women) of postbulbar duodenal ulcer have been studied

Postbulbar duodenal ulcers comprise all those that arise in the duodenum beyond the bulb, though this article is mainly concerned with those in the immediate postbulbar area

Diagnosis depends on awareness of the disease and cooperation between clinician and radiologist

Two groups can be separated out in which a tentative clinical diagnosis can be made

Hæmorrhage group Typically the patient is a middle-aged man with a long history of pain, one or more attacks of bleeding, and usually several negative barium-meal examinations

Intermittent obstructive group Typically the patient is a middle-aged man with a long history of attacks of profuse vomiting and severe pain lasting a few days He is relatively well between attacks, and has usually had several negative barium-meal examinations

The most important symptom is hæmorrhage, for it is often severe and hard to control by medical means Elective partial gastrectomy, if possible, is indicated in most cases

Perforation is rare

We are very grateful to Dr F Pygott and to Dr F Avery Jones for permission to publish these cases, and for their help in the preparation of this article We should also like to record our thanks to Mr J W P Gummer for his advice in the surgical aspects

FLEXION SPASMS AND CONTRACTURES IN SPINAL-CORD DISEASE

Geoffrey Platt

From Stoke Mandeville Hospital, Aylesbury, Bucks

THE late stages of spinal-cord disease—e g, disseminated sclerosis—are often associated with extreme degrees of flexion and adduction deformity of the legs Contractures and spasms combine to cause pain, and they may make the sitting position impossible Distress and deformity are often made worse by loss of sphincter control and bedsores

We have attempted to deal with scores of such patients in recent years, and, since the methods used have slowly become much more effective, it seems desirable to record briefly some of our conclusions

Prevention

We are increasingly aware of the possibilities of prevention Thus a patient with spastic paraparesis who can stand and walk a few steps every day will maintain a predominance of tone in extensor muscles sufficient to prevent any serious tendency to develop flexion spasms Should, however, such a patient have to go to bed even for a few days—e g, on admission to hospital—the lack of standing exercise apparently allows the flexors to ' take over " If the dangers of this situation are not recognised, the spastic flexor muscles quickly shorten, contractures develop, and the patient may never again be able to stand or walk Thus, in cases of spinal-cord disease causing severe paraplegia, a day or two in bed may lead to the permanent loss of all capacity to be other than chair-ridden or even bedfast Hemiplegics, on the other hand, should not be allowed to develop flexion deformities, because all hemiplegics can walk a little, if their general condition allows, and this stimulus maintains extensor tone in the affected leg

When, however, going to bed is unavoidable in a patient with spinal-cord disease, several measures should be taken to counter flexion spasms In the first place, if the general condition permits, a few minutes' weight bearing every few hours is of great value Secondly, all such patients should lie prone for several separate periods each day according to the severity of their disease This posture provides a very powerful counter to flexion movement both by the physical factors involved in this posture and by a physiological tendency for this posture to inhibit flexion It is advantageous to arrange the bed so that the feet hang over the end of the mattress Where adduction spasm is troublesome, pillows may be used to force the knees apart.

The sitting position, in bed or in a chair, should only be allowed for limited periods, because this encourages shortening of these muscles Further, the sitting position increases the hazard of bedsores owing to the increased weight on the buttocks

Correction of Contractures

Once contractures have formed, it is necessary to introduce some extra mechanical force to counter the deforming effect of the muscles involved There are many different ways in which this can be done, but we feel that the following principles may be identified

(1) Prolonged gentle pressure by springs, traction, or turnbuckle plaster is not usually suitable, because the skin will not tolerate the forces required

(2) The skin will, however, tolerate great pressure for limited periods If skilfully applied, such pressure constitutes a very powerful means of countering and correcting flexion contractures Thus, a pressure of 100 lb applied by sling to knee or ankle is well tolerated for 30 minutes, three or four times daily, and this can with advantage be followed by a period of lying prone

(3) One very effective method of pulling out the contracture at the knee, which often develops, is to place the patient prone and to hang a weight on the heel, which is projecting beyond the end of the mattress This effect is increased if vertical upward pull is exerted on the knee through a sling-and-pulley system connected to a weight

(4) Heavy weights might, however, in certain circumstances tear through some of the contracted tissues, so the method described by Russell and Schuster (1951) is safer because the amount of pull is measured and, if the tissues give way, the strength of the traction immediately decreases

Thanks to the devoted work of both physiotherapists and nurses, these and other similar methods have had some striking successes, but for the worst cases several months' treatment has been necessary to pull out the contractures The following case illustrates this

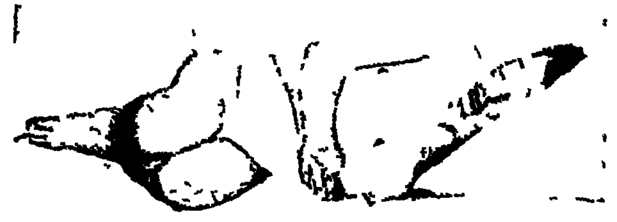

Fig 1—Case 1 condition on admission (April, 1956) showing degree of flexion contracture

Case 1—A soldier, aged 22, contracted tuberculous meningitis while serving in the Army abroad He was evacuated by air on Jan 25, 1955, to the Military Hospital, Wheatley, and admitted under the care of Dr Honor Smith He deteriorated considerably during the flight and was semi-comatose on arrival A prolonged and stormy illness followed Its course was complicated by spinal block of long duration, persistent vomiting, an episode of cerebral hæmorrhage causing dysphasia after intraventricular therapy, decorticate attacks probably of vascular origin, and renal infection with profound disturbance of electrolyte balance During the acute stage of the disease he had more than 350 lumbar, cisternal, and ventricular taps However, the infection was eventually eradicated, and he was admitted to Stoke Mandeville Hospital for rehabilitation on April 6, 1956, fifteen months after the onset of his illness

On admission his general condition was fair, but he was thin and content to lie in bed He had little dysphasia and was partly oriented in time and space but was amnesic for the whole of his time in hospital and abroad (about two years) He read J1 with each eye Both fundi showed mild optic atrophy He had slight bilateral deafness The movements of his arms were excellent In relation to the spinal block which developed during his illness there was now spastic paraplegia and his legs showed severe flexion contracture (fig 1) Strong manual force was needed to overcome the spastic element, but there still remained about 60° of fixed contracture at both hip and knee There was no sensory loss in the legs

Treatment—The deformity was lessened a little each day by various forms of therapy, including repeated stretching on the appliance designed by Russell and Schuster (1951), colloquially known as the "rack" by the ward staff The name is inaccurate because its action is not one of traction, but is exactly comparable to that of applying a downward pressure on the knees of an oarsman on a sliding seat It differs in that the patient lies on his side and the force is applied hydraulically and is virtually isometric

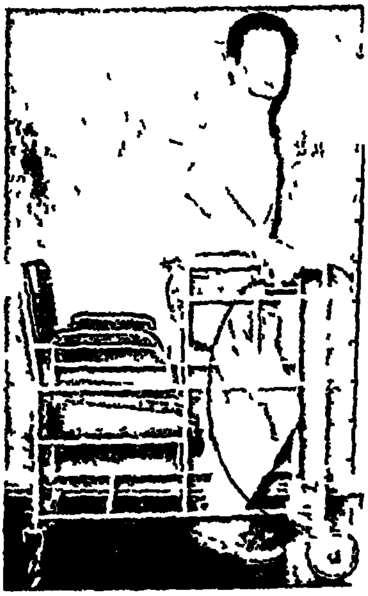

Fig 2—Case 1 in July, 1956

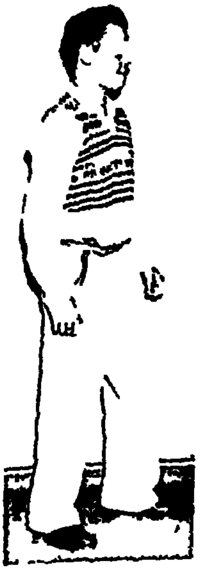

Fig 3—Case 1 in December, 1957

Progress was slow, but the contractures yielded slowly By July, 1956, the patient could move a little in walking plasters, and in December, 1957, he was walking well without plasters Spastic paraparesis persisted but with minimal contracture (figs 2 and 3)

Surgical Operations

Attempts to correct flexion contractures by operation have encountered difficulties Thus division of tendons is often disappointing, and rigid splinting to maintain improved posture after operation may cause necrosis of skin unless the procedure provides sustained reduction of the flexor spasms

It must also be appreciated that discomfort from the surgical incision stimulates flexion spasms vigorously, and the results in the past have often been disappointing

Division of the obturator nerves, however, gives striking relief to the patient who develops severe adduction spasms

Division of lumbar and sacral motor roots relieves all spasm in the legs, without loss of sensation, but the gluteal muscles waste so severely that sitting becomes uncomfortable Large intrathecal injections of alcohol to destroy cauda equina are used in cases of complete transection of the cord (Guttman 1949) but are not suitable for the partial lesions considered here

A striking success has been achieved recently by a combination of operations including neurectomy, tenotomy, and tendon transplant The groups of muscles *most amenable to surgical treatment are the adductors* and flexors of the hip, the hamstrings, and the calf muscles, and the operations used include the following

(1) *Adduction and flexion of the hip*—Obturator neurectomy (Stoffel 1912) alone will relieve adductor spasms, and in bilateral cases without contracture the abdominal approach is used In our cases, however, there is usually contracture of both the adductors and the hip flexors, and for this to be relieved it is necessary to divide the tendon of the iliopsoas muscle to relieve shortening or spasm of this muscle An incision is made over the tendon of the adductor longus muscle, the origins of the adductor longus and brevis muscles are separated from their bony attachments, the anterior and posterior divisions of the obturator nerve are then divided By following the upper border of the adductor magnus muscle one is led to the insertion of the iliopsoas muscle, which can then be divided In closing the wound the origins of the adductors are not sutured back into place After operation gentle assisted abduction and extension, combined with lying prone are practised on the day following operation Standing out of bed is begun on the third day

(2) *Flexion of the knee*—The insertions of the biceps, semitendinosus, semimembranosus, and gracilis muscles are transplanted to the femoral condyles by the technique of Eggers (1952) This may be combined with section of the branches of the posterior tibial nerve to the gastrocnemius muscle After this operation a plaster is well tolerated and is applied from the groin to the toes This is removed after two weeks, and active extension of the knee is begun together with lying prone

(3) *Spastic equinus*—This condition can often be relieved by simple tenotomy of the tendo Achillis This operation causes a shuffling gait with loss of spring in the foot, but this is of little importance in chair-ridden patients This operation may not only relieve painful spasms but also may enable the patient again to walk a little with assistance

Illustrative Cases

The following case-reports illustrate the outstanding advantages of selecting a combination of these operations for cases which do not respond to simple non-surgical methods

Case 2.—A man, in whom multiple sclerosis presented with difficulty in walking in 1937 at the age of 24, walked sufficiently well to be accepted into the Army in 1939 but was invalided in 1941 because his legs became weaker From that time onwards he became steadily worse and he last walked in 1952 with assistance In this year there was an episode of weakness in the left arm, which did not recover completely and so added to his disability He remained at work as a clerk, using an electric chair outside and a wheel chair indoors By 1957 flexor spasms of the legs had become so severe that it was difficult for him to sit in a chair The movement and pain caused by these disturbed his sleep and greatly impaired his efficiency at work

On admission to Stoke Mandeville Hospital on Aug 6, 1957, for assessment he obviously had severe discomfort and pain during the spasms He was demoralised by lack of sleep and appeared tired, pale, and older than his years The positive signs present were nystagmus on lateral and vertical gaze, severe spastic weakness of the left arm with sensory loss of posterior column type, spastic chest and abdominal muscles, and spastic paraplegia with a tendency to flexion contractures Flexor withdrawal of both legs was induced by even light touch on the foot There was little adduction spasm By firm manual restraint the knees and hips could be extended to a minimum of 15 of fixed flexion

Operation on the left leg was done by one of us (G P) on Aug 16, 1957, under general anæsthesia with relaxants The tendons of the biceps and semimembranosus muscles were implanted into the posterior aspect of the femoral condyles, and the nerves to the calf muscles were divided The tendon of the semitendinosus muscle retracted so vigorously into the wound that it could not be implanted A plaster-of-paris cylinder was applied to the limb from the groin to the toes

Postoperatively, incisional pain caused a temporary increase in spasms, but these were reduced by administering pethidine, and they became much less distressing after four or five days The plaster was removed a fortnight after the operation The incision and the skin were in excellent condition There was a striking relief of pain by three weeks after the operation The pattern of the spasm had altered completely, and the frequency was much less There was no flexion of the knee during a spasm The quadriceps was observed to contract, but this was not painful The spasm at the hip was less and no longer uncomfortable. There was little change in the right leg, but the patient could sleep prone for much of the night, which had been impossible before the operation On discharge on Sept 16, 1957, he was just beginning to stand again with assistance He was deliberately discharged to avoid too long an interruption in his employment

Follow-up—When he was seen on Oct 2, 1957, he was distressed by spasm in the other (right) leg and pleaded to have a similar operation on this side also This was done on Nov 8, 1957, the procedure being identical except that it was possible on this occasion to implant the tendon of the semitendinosus muscle in addition to the others

Postoperatively, pain made the spasms worse for a time, but the end-result was the same as that achieved on the left side The patient s general condition improved, and he began to sleep well again Both legs are still subject to slight flexion spasms at the hips, but the movement is small in amplitude He can sit comfortably in a chair and can lie prone quite easily He stood again with support four weeks after the second operation In March, 1958, the improvement was well maintained and he was again at work

Case 3—Multiple sclerosis presented in a woman aged 29 in 1939 with paræsthesiæ in the right arm and leg, stiffness aching, and weakness of the right leg, and weakness of the right hand From 1939 until 1954 or so she had a remarkable series of fluctuations and relapses, often with considerable remission in the intervals From 1954 her disability increased steadily because of increasing paraparesis with frequent flexion spasms causing severe pain in her legs and lower back. In 1954 she would walk several miles and do all her shopping In the three months before admission her walking became much worse.

On admission to Stoke Mandeville Hospital on Aug 25, 1957, at the age of 47, she could walk a few steps with assistance She complained of stiffness and pain in all the muscles from her waist downwards She had difficulty in winding a watch, and her writing had deteriorated considerably

On examination she was mildly euphoric and loquacious The right fundus was pathologically pale. She read J1 with each eye She had a slightly enlarged left pupil and slight left ptosis, but her external ocular movements were full Slight left facial weakness, minimal ataxia on the finger-nose test, and slight impairment of fine finger movement were noted The deep reflexes in her arms were increased except for diminution of the right supinator jerk. Sensation was impaired and was mainly moderate loss of posterior column function Her abdominal reflexes were absent, and her lumbar and abdominal muscles were slightly spastic A partial sensory level was found at T8, with mild loss of perception of all modalities below this Her legs showed severe spastic paraparesis with painful and distressing spasms of forced extension and adduction When these came on she had considerable low back pain. Her deep reflexes were increased, and she had ankle clonus and extensor plantar responses Her general condition was fair except for mild anæmia (Hb 76% = 11 2 g per 100 ml), but she looked tired and unwell

Progress—She unfortunately acquired influenza during treatment soon after admission, and this kept her in bed for a few days, during which she lost ground rapidly and flexion and adductor spasms became dominant over her weak powers of extension Progress with physiotherapy was so slow and she had such considerable distress and pain with the spasms that it was decided to operate

Operation—On Nov 8, 1957, under general anæsthesia the deformities of the hips and knees spontaneously corrected and there was little or no evidence of contracture An incision was made over the tendon of the adductor longus muscle on each side The tendon was divided from its origin and turned down to expose the anterior branch of the obturator nerve. One inch of the nerve was resected and the origin of the adductor brevis muscle was then divided and the muscle turned down to expose the posterior division of the nerve, which also was divided By following the upper margin of the adductor magnus muscle the insertion of the iliopsoas muscle was identified, it was found to be contracted and was divided The patient was then turned on her face An S-shaped incision was made over the popliteal fossa and upper calf on each side This type of incision is used to avoid subsequent contracture of the scar The insertions of the semitendinosus, semi-membranosus, gracilis, and biceps femoris muscles were identified and divided The first three tendons mentioned were transplanted into the posterior aspect of the medial femoral condyle, and the last-named tendon into the lateral femoral condyle The motor branches arising from the posterior tibial nerve, and supplying the [illegible] muscle were [illegible] and divided The [illegible]

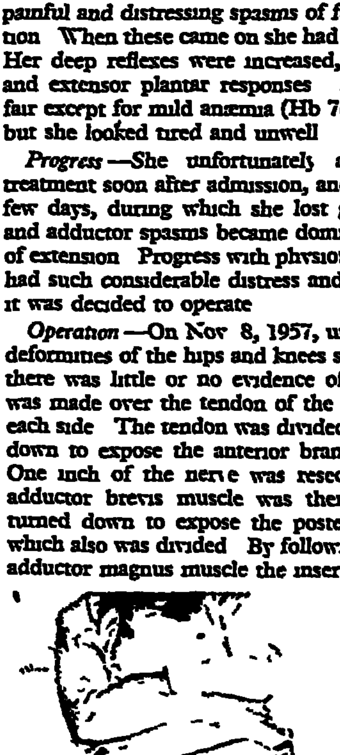

Fig 4—Case 3 preoperative posture during active spasms of right leg note considerable adduction of both legs

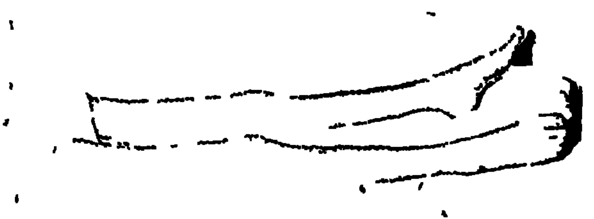

Fig 5—Case 3 postoperative absence of adduction, note extension of both legs (flexor spasm could not be induced)

were then closed, but no attempt was made to re-attach the adductor origins The knees were immobilised in the straight position by padded plaster cylinders

Postoperatively the patient's blood-pressure fell somewhat, and she required methylamphetamine, dextran, and blood to restore her circulation to normal This was probably the result of doing the operations on both sides at one session The patient had been turned twice during the operation There was incisional pain of some severity which caused increased spasm for about ten days, and she required pethidine frequently to control this However, after the plasters were removed, the incisions were found to be in excellent condition, and she began to improve As in case 2 perhaps the most striking improvement was in her general appearance This improvement was parallel with the lessening of her pain Flexion spasm was replaced by extension spasm which was not distressing She began to stand with plasters about three weeks after the operation and can now, five months after operation manage a few steps with assistance (figs 4–6)

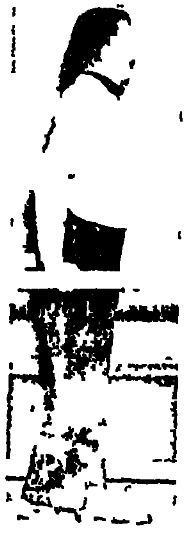

Fig 6—Case 3 standing supported after operation

Discussion

In case 1 the spinal-cord disease was completely arrested, and it proved possible to pull out severe contractures over a period of many months In retrospect, however, it seems that this good result would probably have been obtained more quickly with the assistance of surgery

In cases 2 and 3 there is progressive disease of the nervous system with no prospect of a good recovery of crural functions, and for these we used a combined operation to deal with all the main muscle groups affected This operation not only divided or paralysed the muscles causing deformity but also converted the hamstring muscles from knee flexors to thigh extensors The early postoperative results are most gratifying and much better than any we have achieved by other means Relief of both pain and spasm is most noticeable, and there is every indication that this type of operation can keep these unfortunate patients much more comfortable and active than would otherwise be possible

Summary

In non-progressive cases of flexion spasms good results may be obtained by mechanical devices which apply powerful correcting forces two or three times daily for periods of about 30 minutes each

In severe cases operation may give excellent results by one or all of the following procedures obturator neurectomy, division of the tendon of the iliopsoas muscle, transplantation of the hamstring tendons to the back of the femur, division of the nerves to the gastrocnemius muscle, and section of the tendo Achillis

These combined operations can be used to give great relief to patients with flexion contractures and spasms due to spinal-cord disease

We wish to pay a special tribute to the nurses and physiotherapists, whose tireless interest in helping the patients make these results possible

Volhard (1937) claimed that fasting is one of the most effective means of treating acute glomerulonephritis, and this has often been confirmed After fasting, all the acute manifestations (reduction of glomerular filtration-rate (G F R), hypertension, and œdema) rapidly subside (Brod 1949), but we do not know why Volhard himself thought that an overtaxed circulation was unburdened, but this view is hard to sustain Because the rational basis of this treatment was uncertain, many physicians abandoned or changed it, and some have even suggested that acute fasting might hasten the development of uræmia, as happened in rats that were starved after partial nephrectomy (Persike 1950) or in experimental Masugi nephritis (Dutz et al 1956)

But in acute glomerulonephritis it is less important to prevent uræmia than to shorten the disease The ultimate prognosis of the disease depends on both the intensity and the duration of the acute stage (Brod 1949, Brod et al 1955) which, according to present opinion, is caused by an autoallergic vascular reaction We cannot influence the intensity, but every means of shortening the acute stage must be used

Since fasting seemed to have so great an effect, we thought it worth while to investigate whether fasting interfered with the capacity to produce an autoallergic reaction Many victims of the concentration camps, who had previously had allergies, lost them during their period on a semi-starvation diet (Šmahel 1946)

The autoallergic reaction in acute glomerulonephritis is accompanied by a raised serum titre of certain agglutinins (collodion agglutinins), which may represent anti-kidney antibodies (Cavelti and Cavelti 1945a and b, Lange et al 1949, Lippmann et al 1950, Wagner and Holečková 1951, Rejholec et al 1952) We have, therefore, followed the change of the titre of these agglutinins in the course of therapeutic fasting in acute glomerulonephritis, and compared the course of these changes with the course of the main clinical and functional manifestations of glomerulonephritis

Methods

The patients investigated were treated in our institute, or in the pædiatric department, with enforced strict bed rest Fasting was usually started 24 hours after admission During the first 24 hours in hospital, the patient was kept on a light diet, and basal data of his renal functions and (in most cases) collodion agglutinins were obtained The period of fasting lasted 60 hours, the patients received neither food nor fluid, except for some 100 ml a day of unsweetened fruit-juice They were given no glucose (Pevznĕr (1949) holds that glucose increases the likelihood of allergic reactions)

When the 60-hour period was over, the patients were put on a semi-starvation diet, consisting mainly of fruit and vegetables, and yielding no more than 500 calories, which was continued until all signs of the acute vascular reaction (reduced G F R, hypertension, and œdema) had subsided Only then did we go over to a normal diet or to the quantitative diet of Addis (1948)

As a control we used a group of children from the pædiatric department They were also kept strictly in bed, but were given a light diet with no fasting period Such a diet is used in the treatment of glomerulonephritis by most pædiatricians (Rabinovich and Winter 1950, Mores and Navratil 1952)

From the first day the G F R was estimated by the clearance of endogenous creatinine in 4-hour periods throughout the whole period of observation Daily Addis counts of the urinary deposit were made Blood-pressure and fluid-balance were measured daily

The titre of the collodion agglutinins was estimated (Cannon and Marshall 1940, Cavelti 1941, 1948, Humphrey 1948, Lange et al 1949, Wagner et al 1952, Wagner 1954)

Collodion stock suspension was prepared by the method of Wagner and Rejholec (1952) and Wagner (1954), it lasts 3 weeks This stock solution was diluted with 1 1% saline or Ringer's solution to McFarland's grade-2 density The antigen was prepared from a healthy human kidney, as free from blood as possible, ground up and diluted 1 4 with either saline or Ringer's solution This suspension was kept at −30°C On the day of investigation 1 part of this solution was added to 20 parts of the collodion suspension The antigen-collodion suspension was incubated for 1–2 hours at room temperature The serum to be investigated was diluted geometrically with the saline or Ringer solution To the diluted serum, an equal amount of the incubated collodion-antigen suspension was added (usually 0 25 ml are used) After 2 hours' incubation at room temperature, the test-tubes were centrifuged for 3 minutes at 1200 revolutions per minute The deposit was stirred and examined in reflected light without magnification If the particles were just visible, the result was ±, if the particles formed lumps of 1 5 mm in diameter, the result was ++++ The highest geometrical dilution of serum containing antibodies was usually ±, and this dilution grade is indicated in tables I and II But when there was agglutination at dilutions 1/16 and higher, the lowest dilution usually gave a ++++ result, with at least + in the 1/8 dilution The "dubious" 1/4 titre was the only one where only a ± result was sometimes obtained

Control specimens of the diluted collodion and the collodion-antigen suspension were always examined for spontaneous agglutination Normal sera always gave negative results A titre of 1 4, though never found in normal subjects, was regarded as a dubious result, a titre of 1 8 was regarded as positive (Lange et al 1949, Rejholec et al 1952) The highest titre observed by us in human glomerulonephritis was 1 128

Results

Patients Treated by Absolute Fasting

Of twenty-nine patients with acute glomerulonephritis, four were adults (aged 22–59) and twenty-five children (aged 5–15 years) In twenty patients, a positive titre of collodion agglutinins was found in the serum on the day of admission In two others, in whom the titre was first estimated on the 1st day of treatment, a positive titre was also found Another four had dubiously positive titres of 1 4 The initial titres were negative in only three

Of the twenty-six positive and dubious titres at the beginning of treatment, nineteen became negative immediately after the end of the fasting-period (table I) In

* First estimation on the first day of treatment Neg, negative

seven others the titres definitely decreased The average duration from the start of treatment to the time when the titres became zero was 5 days (range 1–13 days)

Of the twenty-six patients with decreasing titres of antibodies, reliable data on glomerular filtration were obtained in twenty-three By the first day after the end of the fast, the G F R definitely rose in sixteen patients, and in two more an upward trend was probable At the same time the blood-pressure fell to normal and the œdema subsided in all patients but one

A boy, aged 15, had had glomerulonephritis for 10 days when he was admitted Fasting was started 24 hours after admission (fig 1) The titre of the collodion agglutinins started to drop almost at once The G F R averaged 50 ml per min on the day of admission, after a transient fall on the first day of fasting, when the titre of antibodies was still 1 16, it began to increase on the second day and reached 91 ml per min 2 weeks later The blood-pressure, which was 130/90 at the start, fell to 110/70 He had no œdema There was no consistent change in proteinuria or in the Addis count

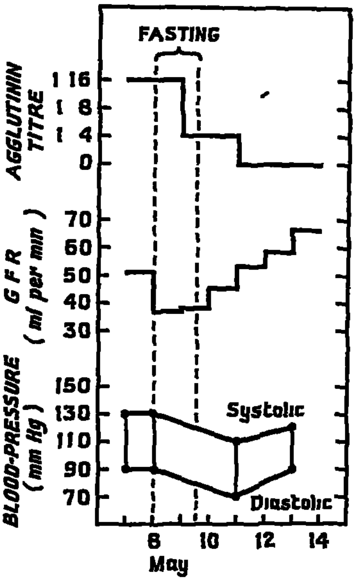

Fig 1—Course of illness in a boy who fasted

In three patients the antibody titre started to rise again when the fasting gave place to a light diet containing plenty of carbohydrate (fig 2)

In three patients whose antibody titres were negative at the start, the fasting had no effect on their G F R

Patients Treated with Bed Rest and Light Diet

This group consisted of nine children aged 5–14 On admission, the agglutinin titre was positive in five, doubtful in one, and negative in four (table II) But in all nine patients the titres became strongly positive in the subsequent days when the children, although resting, were fed a diet rich in carbohydrate

A girl, aged 9 years, had had acute glomerulonephritis for 4 days (fig 3) On admission her G F R was 42 5 ml per min, and the agglutinin test was negative But on the 3rd day of hospital treatment, consisting of bed rest and light diet, the titre became positive (1 8), and 3 days later it reached a maximum of 1 32 The agglutinins did not disappear till the 10th day, and it was from this day on that the G F R started to increase, though a few days later it fell to about 38 ml per min The fall in blood-pressure and disappearance of œdema were slow, lasting up to the 8th and 10th day respectively of the hospital treatment

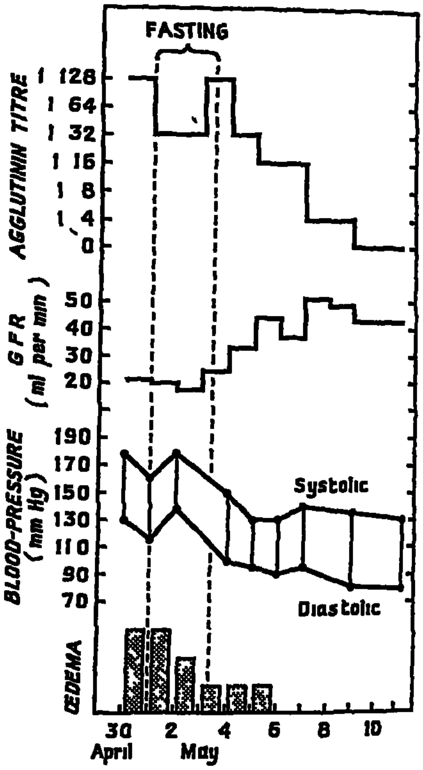

Fig 2—Rising titres when fasting was abandoned

A similarly slow disappearance of the signs of acute glomerulonephritis was found in eight of the nine patients In the 9th patient, a girl aged 13, no improvement was noted over 7 days Fasting was then ordered, and she improved quickly, but the disease became chronic

In three patients the glomerular filtration-rate was lowest at the start, in five there was a further drop during treatment, in one the course was interrupted by fasting, and in one (no 9) the changes could not be followed every day because of technical difficulties Of the eight patients in whom the G F R was followed long enough, there was an improvement in four 3–28 days after admission, but in none was the rate quite normal then Four patients had œdema, and it took 2–12 days to disappear The blood-pressure was raised at the start in five patients In three it subsided after 3–14 days, in one it remained permanently elevated, and in one hypertension disappeared when treatment was changed over to fasting

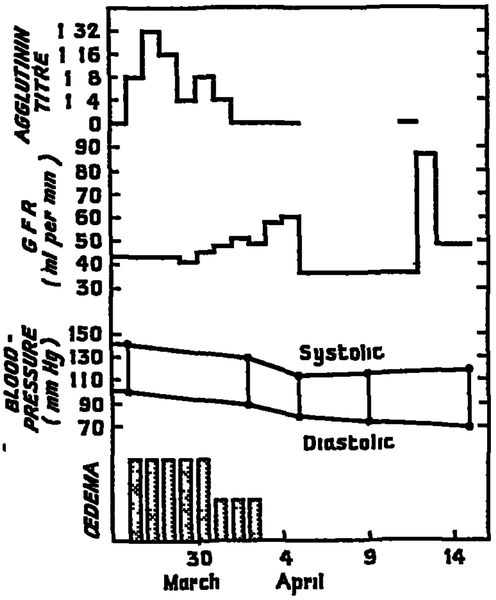

Fig. 3—Course of illness in a girl who did not fast

Discussion

The exact significance of the collodion agglutinins is uncertain, but there seems little doubt that they indicate the presence, and possibly the intensity, of autoallergic processes which form the basis of acute glomerulonephritis Fasting can clearly make these agglutinins disappear At the same time the main clinical manifestations of acute glomerulonephritis—reduced G F R, hypertension, and œdema definitely improved

On the other hand, in nine patients treated only by bed rest and light carbohydrate diet, the titre of agglutinins either remained unaffected or increased, and the clinical course changed more gradually The G F R rarely increased much or became normal within the period of observation Œdema and hypertension continued for longer

The differences between the two groups of patients were compared by the H-test (Wald and Wolfowitz 1944, Kruskal and Wallis 1952, Kruskal 1952), a means of variance analysis In the patients who fasted, collodion agglutinins disappeared significantly faster, and the G F R and blood-pressure returned to normal significantly sooner than in the control patients (table III) Œdema lasted, on the average, 4 2 days in the patients who fasted, and 7 3 days in those who did not, these differences are not significant

TABLE III—SIGNIFICANCE OF DIFFERENCES BETWEEN THE TWO GROUPS

—		Days after admission (average)		
		Disappearance of collodion agglutinins	Duration of	
			Reduced G F R	Hypertension
Fasting		5	6 3	3 6
Bed rest + light diet		10	11 7	8 3
Significance	H	8 271	7 081	5 348
	P	<0 01	<0 01	<0 05

Our observations suggest that therapeutic fasting may interfere with the autoallergic processes and thus shorten the duration of acute glomerulonephritis Further support for this view may lie in the fact that fasting had no effect whatsoever on the clinical course of three patients who had a negative titre of collodion agglutinins on admission (A similar negative result was found in two other patients—in the "latent" phase of chronic glomerulonephritis, with negative titres of antibodies—who were not included in the present series)

Brod (1949) has shown that, while direct manifestations of the generalised acute vascular reaction tend to subside, they leave residual damage in the glomeruli and tubular cells, this improves much more slowly or may become permanent Our data suggest that fasting has an effect only on the course of the early manifestations (reduced G F R, œdema, and hypertension), and does not reduce damage to the renal parenchyma caused in the individual patient by the initial vascular reaction But it seems established that one of the main factors in the ultimate prognosis is the duration of the initial acute vascular reaction in the kidneys We believe that our data show that fasting can shorten this acute stage, and that all patients with acute glomerulonephritis should fast

Summary

We describe a technique for estimating a titre of agglutinins which, we believe, indicate an autoallergic process underlying acute glomerulonephritis

Two groups of patients with acute glomerulonephritis were compared One group was treated by bed rest and light diet, the other was given no food for 60 hours In the fasting group, the agglutinin titre, blood-pressure, and glomerular filtration-rate all returned to normal significantly sooner than in the controls In three patients with normal initial agglutinin titres, fasting did not shorten the illness

We believe that fasting reduces the severity of the antigen-antibody reaction responsible for acute glomerulonephritis, and should be an essential part of treatment

"Reflecting today on the case of a poor woman who had continual pain in her stomach, I could not but remark the inexcusable negligence of most physicians in cases of this nature They prescribe drug upon drug, without knowing a jot of the matter concerning the root of the disorder And without knowing this they cannot cure the patient Whence came this woman's pain (which she would never have told had she never been questioned about it)? From fretting for the death of her son And what availed medicines while that fretting continued? Why, then, do not all physicians consider how far bodily disorders are caused or influenced by the mind?"

After partial gastrectomy, ingestion of a mixture of hot milk and an egg—the fatty meal of the cholecystogram test—can produce a severe attack of " dumping " (Cox and Kerr 1957) The possible effects of gastrectomy on other digestive functions require study, and we have accordingly investigated the behaviour of the gallbladder, especially after a fatty meal, before and after elective gastric surgery

Investigation

Using intravenous cholecystography, two series of films were taken (in some cases three) in 18 unselected patients undergoing gastric operations The first series of films (the immediate preoperative) was taken within twelve days before operation, the second (the immediate postoperative) within twelve days after operation, and the third (the late postoperative) after an interval of not less than six months A series of films consisted of a two-hour fasting film showing the size and position of the gallbladder, followed by six films showing the rate of emptying after a glass of hot milk with an egg The reason for carrying out two series in some patients, instead of three, was the potential danger of excessive radiation, most patients having had a recent previous barium meal

Radiographic Technique

Light diet for three days, avoiding metallic medicines and gassy foods Early morning cup of milkless tea, then fasting for two hours before intravenous injection of ' Biligrafin ' (sodium salt of N N^1-adipic-di-(3-amino-2 4 6-triiodo benzoic acid)), 20 ml of 30% solution No food or drink for two more hours, then first film taken with patient prone Patient then given hot milk and whisked egg, and films taken at intervals of five, ten, fifteen, thirty, forty-five, and sixty minutes in identical position Radiographic factors 65–70 kV, 1 second at 200 mA , with cone

Results

Gallbladder Volume as Shown by Two-hour Film

Partial gastrectomy (*Billroth II, antecolic anastomosis with spur*) —9 cases In 7 there was an immediate preoperative and an immediate postoperative film In 6 of these, the immediate postoperative film showed dilatation of the gallbladder In the remaining case, there was no dilatation in the immediate postoperative film In 6 cases there was an immediate postoperative and late postoperative film The average time between the immediate and late postoperative films was fourteen months In 3 of these there was no increase in the size of the gallbladder, but in the remaining 3 the late postoperative film, compared with the first, showed dilatation of the gallbladder, indicating that the volume had increased since the operation

Partial gastrectomy (*Schoemaker*) —2 cases There was an immediate and a late postoperative film in each case The late film was taken ten months after the immediate In 1 case, the late film showed that the gallbladder had more than doubled its volume since the immediate was taken In the other, the late postoperative film showed no change

Partial gastrectomy and vagotomy —The anastomosis was antecolic with spur 4 cases, with a preoperative and a late postoperative film in each The average interval after operation before the postoperative film was thirteen months This late postoperative film in each case, compared with the preoperative film, showed that the gallbladder had doubled its volume

Vagotomy and posterior gastroenterostomy —3 cases, each with a preoperative and two postoperative films The average interval between the two postoperative films was eleven months Between the preoperative and the immediate postoperative films there was no increase in volume of the gallbladder in 2 cases and a small increase in 1 case The late postoperative film, compared with the preoperative film, showed definite dilatation of the gallbladder in each case—but less striking than the dilatation after partial gastrectomy The Hollander insulin gastric-secretion test indicated in complete vagal section in each case

Of 15 cases in which a preoperative series of films was followed by at least one postoperative series, the gallbladder became much dilated in 14 In 1 case there was no dilatation in the final radiograph nine months after a routine antecolic partial gastrectomy with spur It can be said, therefore, that dilatation of the gallbladder is an almost consistent change after elective gastric surgery, and that this dilatation was progressive in perhaps half our cases The increase in gallbladder volume was an unexpected finding

The follow-up is being continued to ascertain the duration of this dilatation

The volume of the gallbladder can be computed accurately (Boyden 1928, Siffert de Paula e Silva 1949) The table shows measured gallbladder volumes in 4 of our cases after routine partial gastrectomy without vagotomy

Emptying-rate of Gallbladder After Milk-and-egg Mixture

Partial gastrectomy (*antecolic anastomosis with spur*) —9 cases In 7 cases there was a preoperative and an immediate postoperative series, the emptying-rate was unchanged in 2 cases and increased in 5, the increase was striking in 3 of these 5

In 6 cases there was an immediate and a late postoperative series In the second postoperative series, the emptying-rate was further increased in 4 cases, the increased emptying seen in the immediate postoperative series was maintained in 1 case,

MEASURED GALLBLADDER VOLUME IN THE TWO-HOUR BILIGRAFIN FILM

Case	Sex, age, lesion	Radiograph series	Gallbladder		Comments
			Volume (ml)	Position	
1	F 42 G U	First post-operative Second post-operative (10 months)	18 2 49 7	Normal Unchanged	The gallbladder more than doubled its volume in the 10 months after partial gastrectomy
2	M 56 G U	Preoperative First post-operative	51 2 82 1	Normal Unchanged	Over 50% increase in gallbladder volume after partial gastrectomy
3	M 58 D U	Preoperative First post-operative Second post-operative (9 months)	40 5 83 5 71 8	Normal Lower Lower	The gallbladder doubled its volume after partial gastrectomy No progressive increase
4	M 51 D U	Preoperative First post-operative Second post-operative (10 months)	32 3 40 6 73 7	Normal Unchanged Unchanged	Progressive increase in volume after partial gastrectomy, the final volume being more than double the initial

D U , duodenal ulcer, G U , gastric ulcer The operation in each case was partial gastrectomy, Schoemaker in case 1 and Billroth type II with antecolic anastomosis and spur, in the others

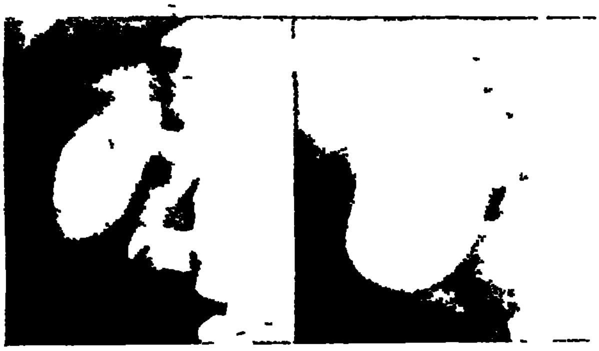
* Based on a paper read before the Manchester Regional Association of Surgeons, June, 1957



(a) (b)

Fig 1—Case 1 Intravenous cholecystogram, 2-hour film (a) 10 days after operation, gallbladder volume 18·2 ml. (b) 10 months later; volume 49·7 ml

and the unchanged rate in the immediate postoperative series remained unchanged in 1 case.

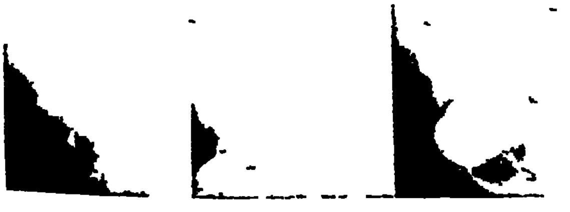
Partial gastrectomy (Schoemaker)—2 cases, with an immediate postoperative and late postoperative series in each. In 1 case in the late postoperative series the rate was increased; in the other there was no change.

Partial gastrectomy and vagotomy—4 cases, with a preoperative and late postoperative series in each case. In 3 cases the emptying-rate was increased and in 1 there was no change.

Vagotomy and posterior gastroenterostomy—3 cases, with three series of films in each. In 1, the emptying-rate was unchanged in both postoperative series. In the remaining 2, the first postoperative series showed no change in 1 case, and a slower emptying-rate in the other. The second postoperative series in each case showed an increase in emptying-rate compared with the preoperative series.

In 15 cases there was an immediate preoperative and one postoperative series, in 11 of these the emptying-rate of the gallbladder was increased after a fatty meal. This increase is mainly limited to the ten-minute and fifteen-minute films, showing that the emptying begins earlier and is more active than before operation. Dilatation of the gallbladder and increase in emptying-rate must be accepted as unrelated changes, because not all gallbladders that are dilated have shown an increase in emptying-rate, and the emptying-rate has increased in undilated gallbladders. No film has shown dilatation of the common duct, at the time of either dilatation or emptying of the gallbladder. There has therefore been no indication at any time of contraction or failure of relaxation of the sphincter at the lower end of the common duct.

The changes in the gallbladder after elective gastric surgery are dilatation, which is often progressive, and an increase in emptying-rate. The gallbladder has apparently moved downwards, by the width of one lumbar vertebra, in 2 cases. The doubling in volume of the gallbladder in 12 days after simple gastrectomy is one of the most striking concomitant physiological changes seen in all abdominal surgery.



(a) (b) (c)

Fig 2—Case 4 Intravenous cholecystogram, 2-hour film. (a) 7 days before operation, gallbladder volume 32·3 ml. (b) 10 days after operation volume 40·6 ml. (c) 10 months after operation, volume 73·7 ml.

Correlation of Changes in the Gallbladder with the Incidence of "Dumping" and Bilious Vomiting

In these 18 patients there has been 1 case of "dumping"—vertigo, leg weakness, and sweats—developing eleven months after partial gastrectomy, and 1 of minor bilious vomiting developing nine months after a Schoemaker partial gastrectomy. This bilious vomiting lasted only two months. In the patient with "dumping" the immediate postoperative film showed that the gallbladder had doubled its size with an increase in emptying-rate. There was no change, however, in the late postoperative film nine months after operation. As the "dumping" developed eleven months after operation, it is almost certain that there were no associated changes in the gallbladder. In the patient with bilious vomiting, the gallbladder had doubled its volume (though it could still actively contract) during the ten months after operation. The bilious vomiting developed nine months after operation, that is, at a time when gallbladder changes were taking place. It is therefore possible that these changes in the gallbladder caused or exaggerated the minor degree of bilious vomiting in this case. But in fully developed bilious vomiting the amount of fluid lost is substantial. It is unlikely that the release of a relatively small additional volume of bile by active contraction of a dilated gallbladder can be a determining factor in the production of striking bilious vomiting.

Discussion

It seems certain that the emptying-rate of the gallbladder depends on that of the stomach. This sequence will account for all the changes in the emptying-rate of the gallbladder reported above after elective gastric surgery. The remaining problem is to explain the dilatation of a gallbladder that has retained its ability to contract.

Fulton (1955) writes

> "When both vagi are cut, the gallbladder responds to the egg-yolk meal in its normal manner, suggesting that in the absence of the parasympathetic innervation the hormonal mechanism is sufficient to cause normal evacuation of the gallbladder."

Johnson and Boyden (1952) conclude that

> 1 Complete severance of the vagi results in progressive enlargement of the gallbladder. They found the fasting volume approximately doubled by complete vagotomy.
>
> 2 The vagi are not essential to evacuation of the human gallbladder, and emptying is regulated primarily through a hormonal mechanism.

It is clear from Mitchell's (1953) diagrams that the vagus supply to the gallbladder runs very close to the left gastric artery, in the cœliac division of the posterior vagus, and in the gastrohepatic omentum. In view of this, it is highly probable that the vagus supply to the gallbladder will be severed once, if not twice, in a routine partial gastrectomy.

Both formal vagotomy and partial gastrectomy therefore produce dilatation of the gallbladder. It seems certain that this dilatation is caused by section of its vagal supply during partial gastrectomy.

In a paper published in December, 1956, when this work was nearly complete, Scott and Whiteside drew attention to the presence of an enlarged gallbladder in 7 cases of postgastrectomy bilious vomiting. No attempt was made to explain this finding It will have been noted that none of our patients had well-established post-gastrectomy bilious vomiting

One additional thought may be committed to paper It seems that, after partial gastrectomy, an excessive amount of cholecystokinin is liberated and causes a very dilated gallbladder to contract to a very small size in ten to fifteen minutes It seems possible that some such active substance, liberated in excess by a fatty meal, may "spill over" into the general circulation and produce the "dumping syndrome" An investigation of the portal stream would throw light on this point

Summary

Gallbladder function after elective gastric surgery has been investigated in 18 patients by means of intravenous cholecystography

The characteristic changes are a dilatation of the gallbladder that is sometimes progressive and an increase in its emptying-rate after a fatty meal

The dilatation is probably caused by section of the vagus nerves, and the emptying-rate of the gallbladder probably depends on that of the stomach

IMPROVED METHOD OF LABELLING RED CELLS WITH RADIOACTIVE PHOSPHORUS

P L Mollison
M D Camb, F R C P

Margaret A Robinson
B Sc Lond

Denise A Hunter

From the Medical Research Council's Blood Transfusion Research Unit, Postgraduate Medical School of London

When radioactive phosphorus is added to heparinised blood and the mixture is then incubated at 37°C, about 30% of the ^{32}P is incorporated in the red cells during the first hour (Hevesy et al 1944, Reeve and Veall 1949, Wilklander 1956) In the course of experiments on the metabolism of red cells in this laboratory it was found by chance that the uptake of ^{32}P by red cells washed in citrate was very much more rapid than this We report here the results of an investigation of the factors concerned in this rapid uptake and describe an improved method of labelling red cells with ^{32}P

Preparation of Red Cells

Red cells were obtained from blood freshly drawn into a heparinised syringe The blood was transferred to a screw-capped glass container and centrifuged The plasma was taken off into a new container, most of the red cells were sucked up from the bottom of the container so as to leave behind as much as possible of the buffy coat, the red cells were then mixed with their own plasma to give blood poor in white cells 2 ml quantities of this blood were used and, as an approximation, it was taken that each 2 ml contained 1 ml of red cells In some experiments the blood was simply packed by centrifugation and the supernatant fluid was discarded before ^{32}P was added to the packed cells In other experiments the red cells were washed by adding about 20 ml of a wash solution to the 2 ml of blood, after centrifugation the supernatant fluid was discarded and the cells were resuspended by adding 1 ml of one of a series of solutions which were being tested

Radioactive Phosphorus

^{32}P was usually obtained without carrier (P B S 1 from the Radiochemical Centre) and was diluted in 0 9% sodium chloride, to which sodium phosphate was added in a concentration of about 0 1 mg per ml as carrier The volume of solution added to 1 ml of red cells was initially 0 1–0 5 ml During the course of the work it became apparent that sodium chloride interfered with the uptake of phosphorus, therefore the ^{32}P with high specific activity was diluted in the following solution

Trisodium citrate 3 0 g
Sodium di-hydrogen phosphate ($NaH_2PO_4 2H_2O$) 0 015 g
Glucose 0 2 g
Water to 100 ml

This solution, which has a pH of about 6 9, is referred to as citrate-phosphate

The diluted ^{32}P solution used in the uptake experiments contained about 5 μC per ml The ^{32}P solution used for labelling red cells for estimation of the red-cell volume contained about 20 μC per ml

Solutions Used for Washing or Resuspending Erythrocytes

To each of the following solutions, glucose in a concentration of 200 mg per 100 ml was added, but, to save repetition, the presence of glucose in the solutions is not mentioned in referring to them subsequently

Citrate-phosphate —This solution was the one described above

Saline-phosphate —1 0% sodium chloride with 0 015% sodium dihydrogen phosphate (pH 6 8)

Saline —0 9% sodium chloride

Potassium chloride —1 14% KCl (this concentration was chosen as being isotonic with 0 9% NaCl)

Citrate —3 0% trisodium citrate

Citrate-saline —1 0% trisodium citrate in 0 9% NaCl Similarly citrate-KCl was 1 0% trisodium citrate in 1 14% KCl

Sodium sulphate —1 7% anhydrous sodium sulphate

Sucrose —6% sucrose This concentration was chosen because in a lower concentration, such as 4%, the red cells were hæmolysed, and in a higher concentration, such as 10%, they tended to sludge

Sucrose-saline, containing 4% sucrose and 0 6% NaCl, was also tested, in a further experiment 6% sucrose to which 0 1% calcium chloride had been added was also tested (*sucrose with* $CaCl_2$)

E D T A —3% ethylene diamine tetra-acetic acid (disodium salt)

Estimation of Rate of Glycolysis

Fresh red cells from heparinised blood were washed either in citrate-phosphate or in saline-phosphate One volume of cells was then resuspended in an equal volume of the solution in which the cells had been washed, and the mixture was incubated at 37°C for one or two hours The glucose concentration of each mixture was estimated by Nelson's (1944) method before and after incubation The hæmoglobin concentration of the mixtures was also estimated, and from this the packed-cell volume was deduced

Localisation of ^{32}P in Phosphate Compounds of Red Cells

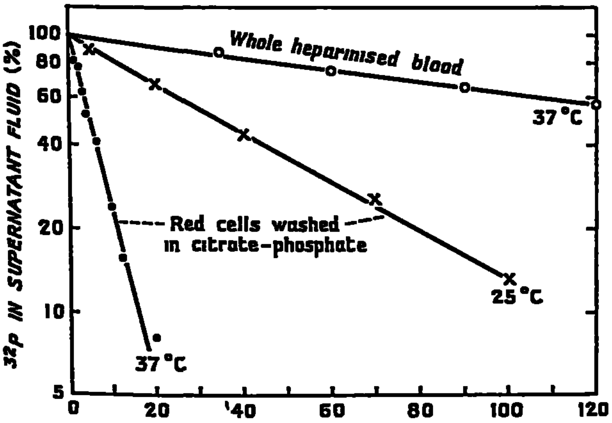
Red cells were washed once in citrate-phosphate and were then incubated with ^{32}P at 37°C for thirty minutes The cells were then washed twice in ice-cold saline The acid-soluble phosphorus compounds were extracted from the cells and fractionated by the method described by Hughes Jones and Robinson (1957) The ^{32}P content of the fractions was also estimated

Estimation of Red-cell Volume

About 20 ml of blood was drawn into a heparinised syringe 10 ml was placed in an empty container, and the other 10 ml was mixed with A C D 3 ml Both samples were spun About 1 ml of red cells was taken from the heparinised sample, the cells were aspirated from the bottom of the container so as to avoid the buffy coat The cells were washed once in 20 ml of citrate-phosphate solution Then to the packed cells was added 2–3 μC of ^{32}P diluted in a volume of

0 1-0 4 ml of citrate-phosphate solution The mixture was placed in a water-bath at 37°C for thirty minutes (fifteen minutes in one experiment) The cells were then washed twice in ice-cold isotonic saline and finally resuspended in about 10 ml of saline solution and added to washed ^{51}Cr-labelled cells (see below)

The sample of blood mixed with A C D was centrifuged and the supernatant fluid discarded To the packed cells about 50 µC of ^{51}Cr was added and well mixed The mixture was left at room temperature for about thirty minutes The cells were then washed twice in saline solution, resuspended in about 10 ml of saline solution and added to the suspension of ^{32}P-labelled cells The mixed suspension of ^{32}P-labelled and ^{51}Cr-labelled cells was then made up to a volume of about 25 ml with saline solution and kept cold until the time of injection 20 ml was injected from a calibrated syringe, and three or four samples of blood were taken from the opposite arm from about ten minutes after injection to about sixty or seventy minutes after injection The packed-cell volume of each sample was determined in duplicate, and the values were corrected for trapped plasma The ^{32}P values, as counts per minute per ml of red cells in each sample, were then plotted on semilogarithmic paper, and the best straight line was fitted to the points by eye From the line the value at 0 minutes was deduced In the case of the ^{51}Cr values it was assumed that there was no significant loss of ^{51}Cr from the circulation during the period of observation, and the ^{51}Cr value was therefore taken as the mean of all the samples expressed in terms of counts per ml



Uptake of ^{32}P in whole heparinised blood compared with uptake by red cells washed in citrate-phosphate (3% citrate with 0 015% sodium dihydrogen phosphate, see text)

Results

The accompanying figure shows the uptake of ^{32}P by red cells washed in citrate-phosphate, compared with the uptake in whole heparinised blood In cells washed in citrate-phosphate, and resuspended in citrate-phosphate, uptake is a simple exponential process with a half-time of five minutes at 37°C, and of thirty-five minutes at 25°C By contrast, in heparinised blood half the ^{32}P is taken up, at 37°C, in two and a half hours The rate of uptake of ^{32}P in red cells washed in citrate-phosphate and left in citrate-phosphate at +4°C is not shown because it was negligible (less than 2% in twenty-four hours)

Some of the results of experiments designed to elucidate the above-mentioned findings are set out in tables I–III, all the experiments were made on at least two separate occasions, and all the results are mean values derived from at least two experiments

When ^{32}P was added directly to packed red cells obtained from heparinised blood, the rate of uptake was considerably increased, thus 79% of ^{32}P was incorporated in the red cells in thirty minutes at 37°C When 0 2 ml of plasma was added to 1 ml of red cells before the ^{32}P was added, the uptake was 42%, the addition of 1 ml of heparinised plasma to 1 ml of red cells reduced the uptake to 12% The addition of 1 ml of 0 9% NaCl to 1 ml of cells reduced the uptake to a similar level On the other hand, the addition of 1 ml of citrate or of citrate-phosphate to 1 ml of cells led to a greatly increased uptake of ^{32}P, the effect of 1% citrate in 0 9% NaCl was intermediate (see table I)

TABLE I—UPTAKE OF ^{32}P BY RED CELLS FROM HEPARINISED BLOOD RESUSPENDED IN VARIOUS SOLUTIONS

Solution added to 1 ml of packed red cells		Uptake of ^{32}P (%)*
Volume (ml)	Composition	
Nil	—	79
0 2	Plasma	42

1 0	Citrate-phosphate	57
1 0	Citrate-saline	30

* After 30 minutes at 37°C.

Effect of Washing Red Cells in Citrate-phosphate

In a series of experiments red cells from 2 ml of heparinised blood were washed once in 20 ml of citrate-phosphate solution The supernatant fluid was then removed, and the red cells were resuspended into various solutions, the results are summarised in table II

The addition of ^{32}P to packed red cells washed in citrate-phosphate invariably led to rapid and complete uptake of ^{32}P Thus in eight experiments the average uptake after thirty minutes at 37°C was 98% When 0 5 ml of citrate-phosphate solution was added to the cells before ^{32}P was added, the uptake was slightly reduced, but even after the addition of 1 ml the uptake was still 87% On the other hand, when saline solution was added to the cells, the uptake was greatly reduced, thus the addition of only 0 2 ml of saline solution to 1 ml of cells reduced the uptake to 51%, and the addition of 1 ml reduced the uptake to 11% When citrate-saline rather than saline solution was added, the uptake was almost as poor as in saline solution alone The addition of KCl produced effects indistinguishable from those of NaCl

Red Cells Washed in Other Solutions

When red cells were washed in sodium sulphate, saline, or sucrose-saline and then resuspended in an equal volume of solution, the uptake was 24–34% On the other hand, when red cells were washed in 6% sucrose or in 3% E D T A and then suspended in 0 5 to 1 ml of the same solution, the uptake was very high

TABLE II—UPTAKE OF ^{32}P BY RED CELLS WASHED ONCE IN 20 VOLUMES OF CITRATE-PHOSPHATE SOLUTION AND RESUSPENDED IN VARIOUS SOLUTIONS

Solution added to 1 ml packed red cells		Uptake of ^{32}P (%)*
Volume (ml)	Composition

1-0 ml	Citrate-KCl	12

* After 30 minutes at 37°C.

TABLE III—UPTAKE OF ^{32}P BY RED CELLS WASHED ONCE IN 20 VOLUMES OF SOLUTION AND RESUSPENDED IN VARIOUS SOLUTIONS

Wash solution	Solution added to 1 *ml* of packed red cells		^{32}P (%) *
	Vol (ml)	Composition	
Sodium sulphate	1 0	Sodium sulphate	28
Saline	Nil	—	74
"	1 0	Saline	27
"	1 0	Citrate	66
Sucrose-saline	Nil	—	73
" "	1 0	Sucrose-saline	24
Sucrose	0 5	Sucrose	98
"	1 0	"	99
"	0 5	Sucrose with $CaCl_2$	98
E D T A	1 0	E D T A	97

* After 30 minutes at 37°C

(97%) The addition of 0 01% $CaCl_2$ to 6% sucrose did not diminish the uptake (see table III)

Rate of Glycolysis

In citrate-phosphate the rate of utilisation of glucose at 37°C was about 30 mg per 100 ml of red cells per hour, and this did not differ significantly from the rate observed in saline-phosphate

Localisation of ^{32}P in Phosphate Compounds Within Red Cells

As described above, cells washed in citrate-phosphate and then incubated with ^{32}P at 37°C were analysed 85% of the ^{32}P was present in the fractions containing adenosine triphosphate and 2 3 diphosphoglycerate The remaining 15% was distributed almost equally between the fractions containing adenosine diphosphate and fructose diphosphate and the fractions containing adenosine monophosphate, inorganic phosphorus, and sugar monophosphates

Rate of Loss of ^{32}P in vitro from Labelled Red Cells

The rate of loss of ^{32}P from red cells labelled by the "new" way (i e , previous washing in citrate-phosphate) was compared with the rate of loss from red cells labelled in the "old" way (simple addition of ^{32}P to heparinised blood) The cells were in each case incubated at 37°C with ^{32}P for thirty minutes, washed twice in ice-cold saline solution, and then resuspended in half their volume of heparinised plasma and reincubated at 37°C The loss from red cells labelled in the new way was a little greater than that from red cells labelled in the old way —e g , after an hour about 8% and 4% respectively

Rate of Loss of ^{32}P in vivo from Labelled Red Cells

Tests were made on seven people 5 healthy volunteers and 2 patients with leukæmia The results are shown in table IV The agreement between the ^{51}Cr results and the results obtained by the "new" method of ^{32}P labelling was extremely close Thus, if the ^{51}Cr value is taken as 100%, the mean ^{32}P value was 100 05%, and the coefficient of variation of the ^{32}P results was 0 9% As table IV also shows, the loss of ^{32}P in the first sixty minutes after injection was 10%

TABLE IV—RESULTS IN VIVO COMPARISON OF ^{32}P LABELLING OF RED CELLS WITH ^{51}CR LABELLING LOSS OF ^{32}P IN 60 MINUTES FOLLOWING INJECTION

Case no	^{32}P counts at 0 min as % of ^{51}Cr counts	^{32}P counts at 60 min as % of ^{32}P counts at 0 min
1	100 0	91

3	100 3	91
4	98 9	90
5	99 9	89 5
6	99·0	—
7	100 9	89 5
Mean	100 05	90

Discussion

Although it is usually held that the uptake of phosphate by red cells depends closely on glycolysis, it is clear that the greatly accelerated uptake observed in cells washed in citrate cannot be directly related to an increase in glycolysis Thus, cells washed in citrate take up ^{32}P about thirty times more rapidly than do cells in heparinised plasma, although their rate of glycolysis is not increased Similarly, cells washed in E D T A take up ^{32}P very rapidly, although in such an acid solution glycolysis must be depressed

The results suggest that the most important factor in the acceleration of uptake is the amount of penetrating anion present in relation to the volume of red cells Thus, packed red cells from heparinised blood take up phosphate well, but the addition of only a fifth volume of plasma to the packed red cells reduces the uptake from about 80% to 40%, and red cells suspended in an equal volume of plasma have an uptake of only 12% (all these figures refer to the uptake after thirty minutes' incubation at 37°C) The effect of isotonic saline, potassium chloride, and sodium sulphate solutions is very like that of plasma On the other hand, E D T A has an effect very like that of citrate These latter substances appear to act simply as non-penetrating anions, because sucrose, which is also a substance which does not readily penetrate the red-cell membrane, has the same effect This suggests that anions such as chloride and sulphate normally compete with phosphate for some transport mechanism and that the uptake of phosphate can therefore be improved by any means which reduces the amount of these competing anions in the fluid in which the red cells are suspended

The improvement in uptake produced by citrate cannot be due simply to the binding of calcium, because the uptake is rapid in the presence of physiological amounts of calcium, provided that the concentration of other electrolytes has been reduced by washing (see experiment with sucrose-CaCl in table III)

The fact that the phosphate is firmly incorporated into organic phosphates within the red cell, even when the uptake is very rapid, is shown by the analyses of radioactivity in organic phosphate compounds Similarly, the fact that the uptake is seven times as rapid at 37°C as at 25°C and that it is virtually arrested at +4°C shows that it does not simply depend on diffusion into the red cells but is an active process

Further evidence on this point is supplied by the observation that glycerol in a concentration of about 6 molar inhibits glycolysis and also inhibits the uptake of ^{32}P in red cells previously washed in citrate (Jones et al 1957)

Estimates of red-cell volume by the new rapid uptake method of ^{32}P agreed very closely with simultaneous estimates made with ^{51}Cr The loss of ^{32}P from the red cells during the first hour after injection (10%) hardly differed from that observed after injecting red cells labelled in the usual way (Mollison 1956)

In a previous paper from this laboratory estimates of red-cell volume, using ^{51}Cr and ^{32}P (Reeve and Veall 1949), were made in 14 people The ^{32}P estimates were higher in 8 and lower in only 2 people (Mollison and Veall 1955) It now seems that most of this discrepancy was due to failure to apply a correction to the ^{32}P standards —to take into account the fact that the standards were diluted in water When solutions of radioactive phosphorus are diluted in blood, as they should be for strict comparison with the samples of blood, their counting-rate is about 0 98 times the rate observed when they are diluted in water If this correction factor had been applied to the previous results, the agreement between the ^{32}P and ^{51}Cr results would have been almost exact It remains true, as pointed out in the previous paper, that the ^{32}P method is liable to give overestimates of red-cell volume because of the tendency of ^{32}P to adhere to particles of dust, white cells, bacteria, &c One advantage of the much more rapid uptake obtained when the red cells are first washed in citrate is that virtually all the activity is incorporated in the red cells, and thus errors from injecting ^{32}P attached to other particles is negligible

Summary

When cells are washed once in citrate and are then incubated with radioactive phosphorus at 37°C, the rate of uptake of phosphorus is very rapid, the process having a half-time of about five minutes This acceleration over the rate normally obtained seems to be due to the removal of competing anions, since it is also produced when the red cells are washed in sucrose

Red cells labelled in this way may conveniently be used for estimating the red-cell volume, because the rate of loss of ^{32}P from such labelled red cells is not significantly more rapid, either in vitro or in vivo, than that observed when red cells are labelled in the usual way

This method of labelling is considerably more convenient than that currently in use Not only is it more rapid but also it is more complete, hence the red cells need less washing Very close agreement with simultaneous estimates made by the ^{51}Cr method was observed in 7 cases

UNILATERAL RENAL INJURY DUE TO TRANSLUMBAR AORTOGRAPHY

C G CLARK
M B Aberd , F R C S E
REGISTRAR, ABERDEEN ROYAL INFIRMARY

THE risks attending translumbar aortography have recently been discussed (*Lancet* 1957, Trippel et al 1957) and the major complications reviewed (Crawford et al 1957) The renal complications of aortography have received considerable attention, and ten deaths from renal failure have been reported by Crawford et al (1957) and Conger et al (1957) Crawford et al consider renal injury to be the commonest significant complication and refer to 12 cases of unilateral renal damage, adding a further personal case There are few reports in British literature on renal complications following aortography Riches (1955) mentions a case of renal failure with recovery, and Roy (1957) and Dormandy et al (1957) give details of 2 further cases The following case is reported because severe unilateral renal damage was sustained which was entirely asymptomatic

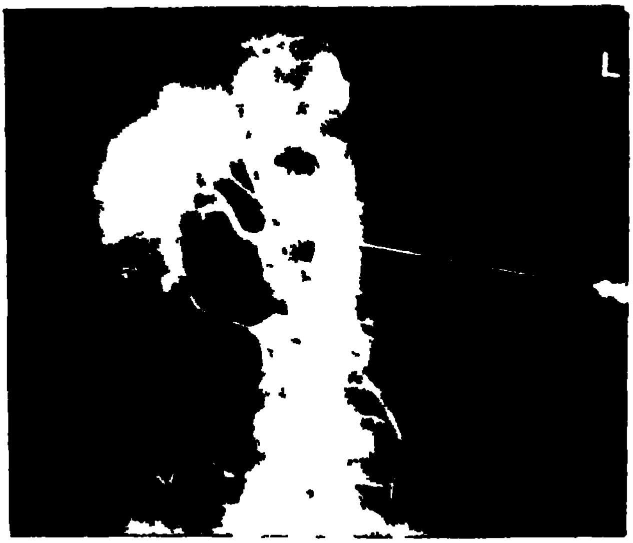

Fig 1—Needle has entered lumen of right renal artery, tip of needle lying at mouth of arterial branch to upper pole Aberrant renal artery supplies lower pole

Case-report

A merchant seaman, aged 64, was admitted to hospital on May 7, 1957, with seven years' history of intermittent claudication affecting his right leg At first confined to his calf it had recently spread to his thigh, exercise tolerance being limited to about 50 yards His foot felt cold and numb, but he had not noted any change in its colour His past medical history was not significant, he had smoked twenty cigarettes a day since adolescence

On examination he was well built, healthy-looking, and inclined to obesity His heart was normal clinically, his blood-pressure 145/85 mm Hg, and his radial pulse regular, with some thickening of the vessel wall All peripheral pulses, including the femoral, were absent from his right leg, and only the dorsalis pedis artery was impalpable in his left leg Thrombosis of either his right common iliac artery or his right external iliac artery was diagnosed

Translumbar aortography was done on May 8, 1957, under thiopentone anæsthesia 50 ml of 70% sodium acetrizoate ('Diaginol') was injected by the one-needle technique using a mechanical pressure apparatus The aortogram is shown in fig 1 The contrast medium had been injected directly into the right renal artery, and the aorta filled by overflow Occlusion of the right common iliac artery and part of the external iliac artery was confirmed The distal part of the external iliac artery and the femoral artery were patent

Progress—After aortography the patient's urine was examined daily, but no abnormal constituents were found, and its specific gravity varied from 1 018 to 1 024 There were no symptoms or signs of injury to the right kidney The output of urine was never less than 800 ml in twenty-four hours, and the blood-urea level was 40 mg per 100 ml Although there was no positive evidence of renal damage, it seemed advisable to postpone intravenous urography rather than subject the kidneys to further exposure to organic iodide The patient was discharged on May 14, there being no suitable homograft then available

Readmission—He was readmitted on June 10, and intravenous pyelography was done, which showed a normal left kidney but poor concentration in the right (fig 2) The urine did not contain albumin, cells, or casts, and its specific gravity was 1 022 The blood-urea level was 41 mg per 100 ml and the blood-pressure 146/80 mm Hg Next day an aortofemoral shunt homograft was inserted to bypass the thrombosed segment Postoperatively the posterior tibial pulse became palpable and has remained so The patient was discharged from hospital on June 30

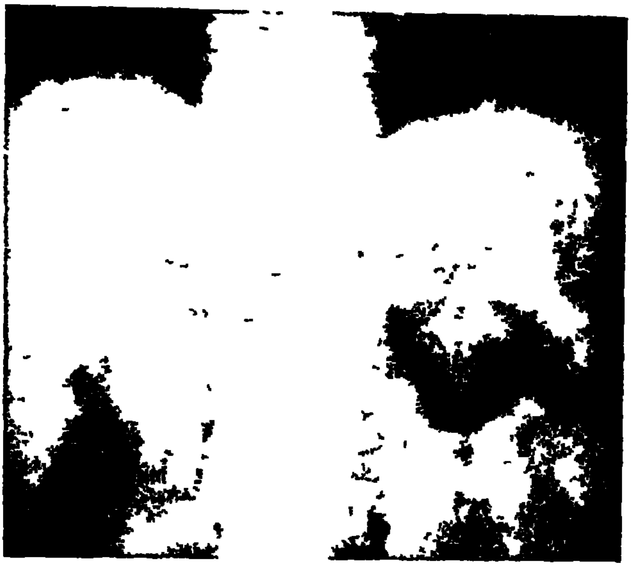

Fig 2—Renal function impaired on right side

Follow-up —On Oct 5 the ureters were catheterised, and indigo-carmine was injected intravenously The dye appeared from the left ureter after six minutes and showed good concentration at the end of an hour On the right side there was no obvious excretion of dye at this time The patient was in good health, and the graft was functioning The blood-urea level was 38 mg per 100 ml

Discussion

The present case illustrates one of the well-recognised complications of aortography and is of special interest in view of the absence of clinical manifestations If the implications of direct injection of organic iodide into the renal artery had not been appreciated, the lesion would possibly have gone unrecognised

In 5 of the 13 published cases of unilateral renal injury complete recovery apparently took place, the 8 others showing either no function or reduced function In the first case an unstated volume of sodium iodide was accidentally injected into the left renal artery, this was followed by pain in the left loin for forty-eight hours, but subsequently phenolsulphonephthalein was excreted normally by the left kidney (Melick and Vitt 1948) In all the other cases the injury was to the right kidney, which is anatomically more susceptible to damage

The factors responsible for renal damage in aortography are considered to be misdirection of the needle, multiple injections, excessive pressure or volume, drug sensitivity, or a combination of two or more of these factors (Miller et al 1954) In all the unilateral cases the needle has been directed toward the origin of the renal artery or has lain within its lumen This hazard is avoidable if the practice of making "scout" injections is adopted as a standard part of the procedure Multiple injections are to be avoided, particularly repeated aortic punctures, as shown by Crawford et al (1957) All the cases of serious hæmorrhage following aortography have been associated with multiple aortic punctures or change in position of the patient with the needle still in place

The use of mechanical apparatus to inject contrast media under pressure has received considerable criticism Many clinics obtain satisfactory films by manual pressure only, and in view of the dangers of aortic dissection, emphasised by Gaylis and Laws (1956), it seems advisable to abandon this technique

Toxicity and idiosyncrasy are difficult to assess Iodism does not appear to be a serious problem, and there have been no deaths from anaphylaxis Organic iodides, however, are harmful in another way, either by destroying tissue directly or by producing ischæmia, and the dosage, concentration, and type of compound responsible for this seem to vary As little as 15 ml of 70% solution of sodium acetrizoate ('Urokon') has been known to impair renal function (McAfee and Willson 1956) and was the medium used in 12 of the cases of unilateral lesions and in many of the bilateral cases

Goodwin (1957) has therefore abandoned sodium acetrizoate in favour of 50% sodium iodomethamate U S P ('Neo-iopax'), although it has been responsible for 1 death (Josselson and Kaplan 1954), and 1 case of unilateral renal injury (Harvard 1953)

80% sodium iodide, so notorious as a cause of death from thrombosis of the superior mesenteric artery in aortography, has been injected directly into the right renal artery without apparent effect (Maluf and McCoy 1955), but a patient cited by Crawford et al (1957) died of bilateral renal injury following the injection of only 15 ml of sodium iodide Idbohm (1956) considers that the use of sodium iodide in renal angiography is unjustifiable

The tolerance to other iodine compounds varies widely from one person to another, and the concentration of the drug is important in this respect (Idbohm and Berg 1954), as well as the type of compound used

So far as renal angiography is concerned, the techniques of selective angiography described by Ödman (1956), Edholm and Seldinger (1956), Tillander (1956) and Gregg et al (1957) seem to offer a measure of safety, but translumbar aortography, still necessary in the investigation of peripheral vascular disease, probably requires a safer contrast medium than is at present available

Summary

A case of unilateral renal injury following translumbar aortography is reported

There was no clinical indication of renal damage

The factors responsible for this lesion are discussed, and the conclusion is drawn that a safer contrast medium is required

I am grateful to Mr G G Bruce for permission to publish, and to Mr G E Mavor for his criticism and advice

CARDIAC SYNCOPE AFTER SWALLOWING

A. H. JAMES
D.M. Oxon., M.R.C.P.
DEPUTY DIRECTOR OF MEDICAL UNIT, ROYAL INFIRMARY, CARDIFF

THIS report describes a patient who had many attacks of cardiac syncope immediately after swallowing food or fluids. A midœsophageal diverticulum was found. Two descriptions of similar cases have been published (Weiss and Ferris 1934, Correll and Lindert 1949), but the syndrome is rare and interesting enough to merit a third.

Case-report

In October, 1955, a lorry driver, aged 58, had pain in his chest while loading a lorry. The pain passed off with rest but recurred two days later. On each of the three following days it came on while he was at rest, it was severe and accompanied by vomiting, and each attack lasted progressively longer, until finally pain persisted all night.

On admission to hospital on Oct. 11, 1955, short of breath and cyanosed, he showed signs of heart-failure his pulse-rate was 120, pulse regular, and blood-pressure 95/70 mm. Hg. Loud pericardial friction was heard. Electrocardiography showed an extensive transmural anterior myocardial infarct. Radiography of his chest showed that his heart was enlarged.

Treatment and progress.—He was given digitalis, mersalyl, and anticoagulants and improved steadily. Ventricular extrasystoles appeared and were sometimes numerous. Thirteen days after admission, while being fed with a breakfast of boiled egg, he suddenly fell back unconscious on his pillow, he threw his arms outwards, and his eyes turned up. He recovered in about a minute. Questioned afterwards, he remembered having had a short attack of unconsciousness forty years before, which he thought had occurred while he was at lunch. Otherwise his convalescence was uneventful. He was discharged on Nov. 21, 1955, free from heart-failure and still taking digitalis folia gr. 1 daily.

Readmission.—In August, 1957, he was sent for consultation because of attacks of fainting. These had started soon after his discharge from hospital, at first they had been infrequent but latterly almost daily. Without exception they had come on while he was either eating or drinking. They were slightly less common with liquids than with solid food, and it made no difference whether the food was hot or cold. His wife said that she had come to be afraid to put food before him. Immediately after swallowing he would feel discomfort which began behind the lower end of his sternum, and seemed to rise towards his throat. Sometimes he would feel faint without losing consciousness, in a more severe attack he would suddenly become unconscious. His wife said that at the beginning of the attack his face would become pale, while he was unconscious his eyes turned up, and he might have a convulsion sufficiently violent to knock the meal off the table. Sudden flushing of the face heralded his return to consciousness. The attacks lasted from one to five minutes, tending to last longer as time passed. Apart from these attacks the patient had been well, was no longer breathless, and had no pain in his chest. He was still taking digitalis.

On examination there were no signs of heart-failure, his pulse-rate was 72, and pulse regular, a soft systolic murmur was heard at the apex, and his blood-pressure was 120/80 mm. Hg. Pressure on either carotid sinus slowed the pulse but caused no faintness. Electrocardiography showed inverted T waves in leads S_1, aVL, and V_3—presumably a sequela of the infarction. There was sinus rhythm except for rare multifocal ventricular extrasystoles, the P-R interval was 0.14 sec. Pressure on either carotid sinus slowed the pulse-rate from 75 to 45 per min. and caused the P wave in the only lead examined (SIII) to become biphasic, the P-R interval was not altered. The effect of drinking cold water for about 5 seconds was then observed three times. The first drink caused asystole lasting 5.6 seconds. This was preceded by three beats in which no P waves were visible in the tracing, which was somewhat disturbed by the activity of drinking. The ventricular complexes were unchanged. At the end of the asystole six beats passed before the P waves reappeared, and of these the second was a ventricular extrasystole. The second and third drinks produced changes similar to those caused by sinus pressure, the heart beat did not again stop. Radiography of the chest showed only slight cardiac enlargement. A barium swallow showed a traction diverticulum of the œsophagus at the level of the bifurcation of the trachea (fig. 1).

Treatment and progress.—The digitalis was stopped, and the patient was given ephedrine, gr. 1/2 t.d.s. During the subsequent eight weeks he had no attacks of fainting, although he sometimes had momentary discomfort in his chest while eating.

Investigation with balloon.—An observation was made (after stopping the ephedrine for two days) in which a balloon 6.3 cm. long and 3.4 cm. in diameter was placed in the œsophagus, inflation of it with 20–30 ml. of air caused, in severe form, the same retrosternal discomfort which initiated his attacks of fainting. With the balloon at the level of the diverticulum the first inflation caused heart-block for three beats, slowing the auricular rate from 88 to 52 without altering the P waves (fig. 2). A second inflation caused heart-block for two beats. The balloon was then moved to a point 4 inches below the diverticulum, the position being checked radioscopically. The first inflation at this site caused heart-block for one beat, followed by a lengthening of P-R interval for three beats, a second inflation only slowed the rate. The balloon was then inflated ten times at the lower site and five times at the level of the diverticulum, the heart beat being observed by auscultation, each inflation slowed the rate, but there were no missed beats.

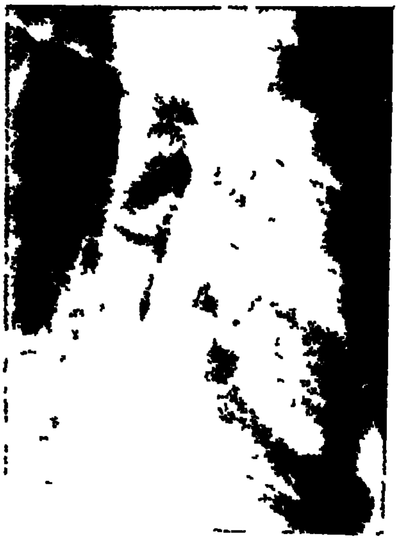

Fig. 1—Barium swallow, showing traction diverticulum of œsophagus at level of tracheal bifurcation.

Discussion

Except that his attacks (with one possible exception) followed a myocardial infarction, this patient closely

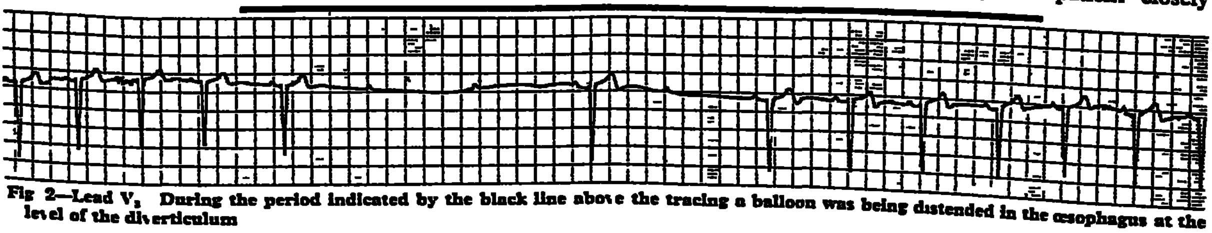

Fig. 2—Lead V_3. During the period indicated by the black line above the tracing a balloon was being distended in the œsophagus at the level of the diverticulum.

resembles those described by Weiss and Ferris (1934) and Correll and Lindert (1949) The œsophageal diverticulum presumably causes the attacks by becoming distended with food and drink, although it has not been shown either in the present patient or in those cited that such distension is the stimulus Weiss and Ferris showed that blocking the vagi in the neck abolished the cardiac response to œsophageal distension, therefore the response was not due to stimulation of motor vagal fibres

In the present patient œsophageal distension did not always cause the same disturbance of conduction Sometimes sinu-auricular block resulted and sometimes auriculo-ventricular block, either change could cause ventricular standstill The change in shape of the P waves during drinking was presumably due to a shift of the pacemaker, a similar effect was observed by Correll and Lindert

A further question is why the attacks started after the myocardial infarction This lesion may have altered the sensitivity of the cardiac impulse to vagal control, or made ventricular escape more difficult A more likely explanation is that the heart was sensitised by digitalis Correll's and Lindert's patient started having attacks eight months after being digitalised, and it was no longer possible to produce faintness by distending the œsophagus after stopping digitalis

The description by Adams and Stokes of fainting attacks accompanied by slowness of the pulse were antedated by three others

Thomas Spens (1793) reported a man, aged 54, who had had three attacks of unconsciousness and whose pulse-rate was 24 The patient had further attacks, one while drinking an infusion of camomile, and one after taking 30 drops of spiritus ammoniæ aromaticus in 2 oz of water Later, feeling better, the patient sat down to dinner

> " upon taking some broth, he almost instantly felt faint, and had the same most distressing sensation as if one of his former fits were coming on The same circumstances took place twice afterwards, on his attempting to swallow something solid About eight in the evening, wishing again to try what would be the effect of swallowing while I was present, he took a bit of newly toasted bread But he had no sooner smelt it, than he felt some of the sensations of a beginning fit, and as soon as he had tasted it he almost instantly cried out, and fell back senseless, with smart convulsions of all his muscles He apparently recovered, however, in a few seconds, but hardly any pulse could be felt for a good many seconds "

He died two days later

> " the body was opened by Mr Fyfe, and, upon the most careful examination, no morbid appearance, of any consequence, could be discovered, either in the thorax or abdomen "

One does not know whether Mr Fyfe would have regarded an œsophageal diverticulum as of any consequence

Summary

A patient is described who had many attacks of cardiac syncope while eating or drinking, he had an œsophageal diverticulum

The attacks ceased when the digitalis which he was having was stopped and he was given ephedrine

Making him drink water and, alternatively, distending a balloon in his œsophagus caused heart-block and ventricular standstill

Previously reported cases are mentioned

I am grateful to Dr A S Bligh for the radiological investigation, Mr R Marshall for the photographs, and Prof Harold Scarborough for advice

THE AIRWAY IN TONSILLECTOMY

A TECHNIQUE FOR CHILDREN

Kenneth Rotter
M B Lond, F R C S, D L O
SURGEON TO THE EAR, NOSE AND THROAT DEPARTMENT, WEST LONDON HOSPITAL

Laurence Mountford
M B Cantab, F F A R C S, D A
CONSULTANT ANÆSTHETIST, LONDON CHEST HOSPITAL

Last year Doughty (1957) described a modification of the tongue-plate of the Boyle-Davis gag which allows oral intubation for tonsillectomy in children We had been using a similar technique with standard apparatus, and we here describe how a satisfactory airway can be maintained through an orotracheal tube lying unseen beneath the tongue-plate of an ordinary Boyle-Davis gag

Careful attention to certain details is necessary

(i) An ordinary Magill tube *fitted with a Magill's nasal* connecting-piece is passed through the mouth and is fixed carefully in the midline by strapping immediately below the lower lip It is then connected to the anæsthetic apparatus in the usual way

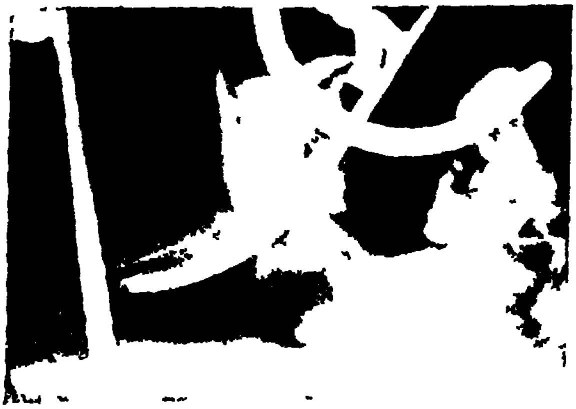

Fig 1

(ii) The Boyle-Davis gag is now introduced, the tube and tongue being retained in the midline as in Doughty's method

(iii) The gag may now be opened as wide as the surgeon requires, the tube lying unseen in the field of operation

(iv) The distal end of the gag is supported by any available mechanical means, but it must not be raised excessively or the tube will be kinked where it emerges from under the tongue-

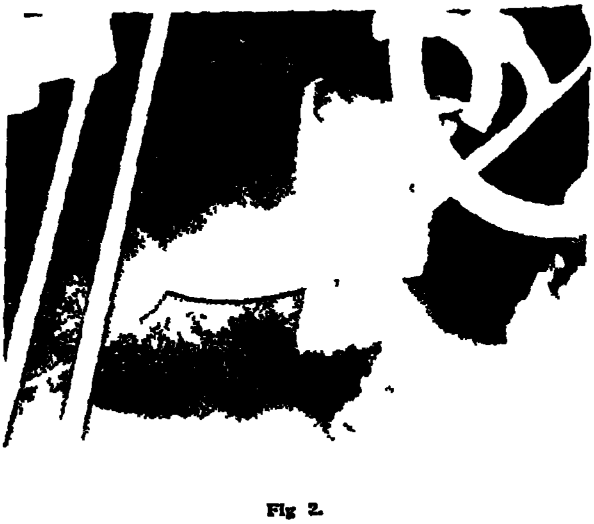

Fig 2

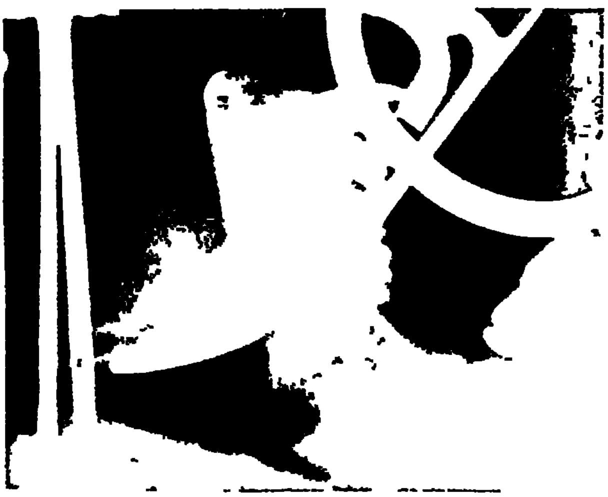

Fig 3

plate to enter the larynx One great advantage of this is tha the pillars of the fauces are thus relaxed, thereby aiding the surgical dissection

Fig 1 shows an ordinary Magill tube actually in use Despite a faint dent in the orotracheal tube *beyond the tip* of the tongue-plate, respiratory sounds were normal and chest movements free and unobstructed Fig 2 shows the effect of raising the tongue-plate hook too far and the mechanism of obstruction thus deliberately caused Obstruction does *not* occur between tongue and plate Fig 3 shows a McIntosh-Oxford tube in use This has a more sturdy wall and is perhaps to be preferred for this technique, though not essential

With colleagues, we have now used this method routinely for all children up to 14 years old without incident and with complete success It has all the advantages of intubation, but the surgeon is unaware of the presence of a tube in his field of operation One of us (K R), who has used the method both with the standard tongue-plate and with the slotted tongue-plate, has found the results equally satisfactory with either

Our thanks are due to Dr J V I Young for suggestions, to the radiological department of Poplar Hospital, for taking the films, and to Mr D Kemp, of the Institute for Diseases for the Chest, for the prints

Preliminary Communication

LIPOPROTEIN-BOUND CHOLESTEROL IN HÆMOPHILIC SERUM

POSSIBLE ætiological factors in atherosclerosis are intravascular coagulation of blood [1] and alterations in the blood lipids, particularly in the lipoprotein fractions of plasma and their bound cholesterol [2,3] An increase in the amount of total cholesterol in the serum with an increase in the cholesterol content of the β-lipoprotein appears to be commonly associated with developed atherosclerosis, these parameters may be an indication of the state of the arterial tree It is therefore of interest to know whether there is any deviation from the normal cholesterol-lipoprotein pattern in the serum in persons with inherited or congenital deficiencies of blood coagulation such as hæmophilia Information on the occurrence and extent of atherosclerosis or cholesterol-lipoprotein abnormalities in such people is scanty Stewart and Acheson [4] reported the finding at necropsy of severe atherosclerotic changes in an elderly hæmophiliac and gave values for the total and lipoprotein-bound cholesterol

I report here the results of an investigation into the cholesterol content of the α and β lipoproteins of serum in a group of hæmophiliacs and compare them with similar observations in healthy people examined concurrently

MATERIAL

The healthy people were men aged 19–50 (mostly 20–30)

The hæmophiliacs were all men with moderate to severe disease and aged 21–68 (see accompanying table) The clinical diagnosis was confirmed and the type (hæmophilia A or B) determined by finding a blood thromboplastic defect due to a deficiency of either antihæmophilic globulin (hæmophilia A) or Christmas factor (hæmophilia B)

METHODS

Thromboplastin formation was measured by the method of Biggs and Douglas [5] with the additional modification of Bell and Alton [6]

Collection of Serum—Blood was aspirated from an antecubital vein and allowed to clot in a dry glass tube at 37°C for several hours The serum was then separated and either analysed on the same day or stored at −25°C for periods up to several months before being analysed

Analysis of Serum—The lipoproteins were separated by paper electrophoresis, and the cholesterol contents of the α and β lipoprotein fractions were determined by a slight modification of the method described by Boyd [7] Total cholesterol was taken as the sum of the α and β lipoprotein-bound cholesterol The observed cholesterol concentrations were probably somewhat lower than the true values because it was unlikely that the cholesterol was completely extracted from the electrophoretic strip

RESULTS

Healthy people—In 26 men the mean total cholesterol was 173 mg per 100 ml (range 75–272, standard error of the mean ±9 5) The mean percentage cholesterol bound to the β-lipoprotein was 78 2 (range 66/89, standard error of the mean ±0 5)

Hæmophiliacs—The individual data are shown in the accompanying table The mean total cholesterol was 134 mg per 100 ml (range 78–159, standard error of the mean ±7 6) The mean percentage cholesterol bound to the β-lipoprotein was 75 6 mg per 100 ml (range 64–85, standard error of the mean ±2 2)

AGE, TYPE, SERUM-TOTAL-CHOLESTEROL, AND PERCENTAGE CHOLESTEROL IN THE β-LIPOPROTEIN IN 9 HAEMOPHILIACS

Case no	Age (yr)	Hæmophilia type	Total cholesterol (mg per 100 ml)	% cholesterol in β-lipoprotein
1	21	B	124	77
2	22	A	78	70
3	24	B	153	82
4	29	B	131	64
5	29	B	154	77
6	30	A	128	72
7	46	A	153	73
8	48	A	125	80
9	68	A	159	85

The total cholesterol values of the two groups were statistically different (p < 0 05 > 0 01) There was no significant difference between the values for the percentage cholesterol bound to the β-lipoprotein ($p > 0\ 05$)

DISCUSSION

The significantly lower mean cholesterol level in the hæmophiliacs may be a fundamental difference and related in some way to the disturbance of coagulation However, since an early age these patients have had numerous episodes of bleeding with severe physical stresses and probably poor dietary intake during these periods The difference may therefore merely reflect the direct and indirect effects of recurrent loss of blood with frequent periods of ill health resulting from the nature of the disease In contrast, the percentage distribution of the cholesterol in the α and β lipoproteins showed no significant difference between the two groups The values for both the total and the β-lipoprotein-bound cholesterol in the serum appear to be above the normal range in the atherosclerotic hæmophiliac reported by Stewart and Acheson[4] None of the present hæmophiliacs had symptoms suggesting coronary-artery disease or vascular insufficiency elsewhere X-ray examination of the aorta in the 3 oldest hæmophiliacs did not reveal calcification, this negative finding does not, of course, exclude the possibility of underlying atherosclerotic changes

The data obtained in this study do not necessarily mean that the hæmophiliacs are less disposed to the development of atherosclerosis or possess less of it than do members of a healthy group comparable in age and sex Accurate correlation can only come from direct examination of the arterial tree Nevertheless the present information may be of some value when more pathological evidence is available and other, perhaps larger, series are reported from other sources

The predictive value for atherosclerosis of the amount and distribution of cholesterol in the lipoprotein fractions of serum has still to be assessed Furthermore intravascular coagulation of blood may be independently related to the development of atherosclerosis

SUMMARY

The amounts of total and lipoprotein-bound cholesterol in the serum were determined in healthy people and in hæmophiliacs

The mean total-cholesterol level in the hæmophiliacs (134 mg per 100 ml) was significantly lower than that in the healthy people (173 mg per 100 ml) The percentage cholesterol in the β-lipoprotein of the hæmophiliacs (75 6) was not significantly different from that of the healthy people (78 2)

I wish to thank Prof J S Mitchell, F R S , *for facilities for this work, and Miss Sheila Tomlin for technical assistance The work was done during the tenure of an Elmore Research Studentship*

Medical Societies

THE HEBERDEN SOCIETY

At a meeting of the society on Feb 14, three papers were presented

A New Phenylbutazone Analogue

Dr D M **Burley** had compared phenylbutazone with its metabolite *p*-hydroxyphenylbutazone (designated G27202), which had been reported to have a similar antirheumatic, but more potent uricosuric, effect than phenylbutazone itself G27202 had been substituted for phenylbutazone dose for dose (usually 200–400 mg daily) for from five days to several weeks, in 72 patients with rheumatoid arthritis and ankylosing spondylitis In relief of pain 9 patients found G27202 more effective, and 23 found phenylbutazone more effective, 18 patients considered them equally effective, and 22 found neither effective or the effects variable 56 patients had no gastric intolerance to either compound, and 16 had intolerance to phenylbutazone, of these 16 patients, 8 were intolerant to G27202, but only slightly in 4 G27202 was less effective than phenylbutazone in relieving pain and stiffness in these conditions, but had about half the gastric toxicity

Uricosuric Agents in Gout

Dr G D **Kersley**, Dr E R **Crook**, and Dr D C J **Davey** (Bath) had investigated the effects of G28315, a phenylbutazone analogue, on the clinical condition, urinary uric-acid excretion, and serum-uric-acid levels of 15 patients with typical gout In the 13 with normal renal function the average daily urinary excretion of uric acid rose from 551 mg to 880 mg on a daily dose of 400 mg of G28315, 5 were given 800 mg daily, and in them the daily excretion rose to 1042 mg The average level of the serum-uric-acid fell from 7 8 to 4 0 mg per 100 ml (After 1–1 5 g of probenecid daily the average serum-uric-acid levels fell from 7 8 to 5 2 mg per 100 ml) The response to G28315 in the 2 with impaired renal function was also very satisfactory Intermittent administration for three days in each week did not maintain the lowered serum-uric-acid level No toxic effects were observed on continuous administration of G28315 for periods of four to fourteen weeks, and longstanding joint swellings regressed Acute gouty attacks increased in frequency during the first six weeks, but thereafter these became mild and infrequent, they were promptly terminated by phenylbutazone in all cases The addition of aspirin 3 5 g daily reversed the effects of G28315, and the urinary uric-acid excretion fell below, and the serum-uric-acid level rose above, the control levels

Rheumatoid Polyarthritis with Negative Agglutination Test

Dr A St J **Dixon** had studied all inpatients of the Rheumatism Research Centre at the Manchester Royal Infirmary who had active and progressive polyarthritis with an increased erythrocyte-sedimentation rate and negative sheep-cell agglutination test (S C A T), and in whom no diagnosis was made relevant to the polyarthritis except rheumatoid arthritis (R A)

Of 64 such patients 6 had died and 51 were seen again after an average of five years, when 13 had developed a positive S C A T—of whom most had a distribution of arthritis typical of R A , and half had developed nodules 18 had typical R A and a negative S C A T , none of these had subcutaneous nodules but most of them had flexor-tendon lesions in the hands 15 had an atypical distribution of arthritis and negative S C A T without nodules or flexor-tendon lesions of any sort 11 patients had developed confirmed or probable polyarthritic diseases other than R A including psoriatic arthritis, reticulohistiocytosis, myelomatosis, generalised osteoarthritis, and gout

Dr Dixon concluded that (1) other diseases may simulate rheumatoid arthritis very closely and a negative S C A T may alone indicate the difference, (2) there is a group of patients, requiring further study, with severe polyarthritis which does not fit the clinical and serological picture of R A , (3) a negative S C A T is compatible with severe or fatal disease in otherwise typical R A , and (4) no difference in prognosis was found in patients with typical R A between those whose S C A T was initially negative and later positive, and those in whom the S C A T was negative throughout It was among the 15 cases with a negative S C A T , who also had atypical R A , that some of the severest illnesses and most dramatic remissions were found

Reviews of Books

Modern Trends in Gastro-enterology

Editor F AVERY JONES, M D, F R C P, physician, Central Middlesex Hospital, and consultant in gastroenterology to St Mark's Hospital, and to the Royal Navy London Butterworth 1958 Pp 439 78*s* 6*d*

THE second series appears five years after the first, under the same able editorship The first volume gave a remarkably wide and clear review of most aspects of gastroenterology the second is complementary to the first, but the editor has this time aimed at picking out only certain growing points of the subject, large or small, where advances or new knowledge have been achieved It is thus a book more for the specialist than the general practitioner, but is none the less valuable and important for that indeed, it is exactly the type of collected information that is badly needed

Dr Avery Jones has gathered a team of 39 authors, most of whom are engaged in research on the subjects about which they write Most belong to the younger school of scientists or clinicians in this country, but Dr Jan Waldenström, of Sweden, contributes a fine article on carcinoid, and six of the authors are distinguished physicians from North America Of new work, that on the blind-loop syndrome (Dr John Badenoch) and on the metabolic effects of intestinal resection (Dr W P U Jackson) make fascinating reading, and so does the account by Dr Sheila Sherlock of hepatic coma and liver-failure Ulcerative colitis receives a full discussion which brings together much material and differing opinions on this difficult disease, but it is clear that no fundamental advance has yet been made towards solving its ætiology

Some rarities rightly receive attention, such as the Peutz-Jeghers syndrome, but for the most part this book deals in a clear and practical way with the main aspects of modern gastroenterology, clinical, pathological, radiological, or chemical It deserves a warm welcome and its editor and authors are to be congratulated on a splendid achievement

Atlas of Clinical Endocrinology

H LISSER, M D, clinical professor emeritus of medicine and endocrinology, ROBERTO F ESCAMILLA, M D, clinical professor of medicine, University of California School of Medicine, San Francisco St Louis C V Mosby London Henry Kimpton 1957 Pp 476 £7

MANY endocrine disorders need pictures to describe them effectively here each condition is illustrated by clinical photographs, sometimes in series, showing the evolution of the disease and the results of treatment Radiographs, electrocardiograms, pathological specimens, graphs, or genealogical tables are often included in the same photographic plate The quality of the reproductions is generally satisfactory but not outstanding (the colour plates of Addison's disease and Cushing's syndrome could be improved) The text, in table form, is on the whole comprehensive and accurate Physiological and chemical aspects of the subject are deliberately omitted, which is a pity perhaps, now that clinical endocrinology has the status of an applied science

The section on hypopituitarism suffers from too much classification into different types, and cachexia is overemphasised as a feature of the disease It is not clear that some of the patients depicted have not in fact anorexia nervosa or functional hypothalamic disturbance Elsewhere there are points of emphasis or omissions that might be corrected Distinction is not clearly drawn between sporadic cretinism and childhood myxœdema, and epiphyseal dysgenesis is not mentioned, with thyroid disorders The section on treatment of adrenal crisis does not refer to the use of intramuscular cortisone acetate as a depot or to tapering of dosage The account of phæochromocytoma omits sweating as a cardinal symptom and erroneously describes flushing (instead of pallor) in the attacks The discussion of the pathogenesis of congenital adrenal hyperplasia is not up to date, and the essential failure of testicular maturation is not brought out

The sections on gonadal disorders are probably the best in the book, though the chapter on the undescended testicle does not emphasise the distinction between failure of the spermatic cords to lengthen and the migration of the testes into ectopic situations—the management of these types being fundamentally different The book ends with a section on miscellaneous non-endocrine disorders, and a useful appendix containing growth curves and tables of height-weight-age, bone-age, and dental age

Human Histology

A Textbook in Outline Form LESLIE BRAINERD AREY, PH D, SC D, professor emeritus of anatomy, Northwestern University, Illinois Philadelphia and London W B Saunders 1957 Pp 337 45*s* 6*d*

IN an interesting preface, Professor Arey explains to some extent the sense of disappointment and disagreement which the text will evoke in some readers There are no illustrations, and the style is as terse as a series of memoranda, whose relative importance is marked by varying degrees of indenting the book is, in fact, a derivative of duplicated sheets of typescript As its author claims, " What may, perforce, be lost in smoothness and grace of style is offset by Baedeker-like concision and force and, it may be hoped, clarity " These hopes are fully realised, but it should not be overlooked that Baedeker-like books inform rather than develop comprehension No doubt Professor Arey supplied other elements than mere information in his courses, but without an assurance of this in other places we hesitate to recommend his largely descriptive catalogue of the tissues of the body, for all its immense collection of information

It is disappointing to find that it is still necessary to devote 337 pages to an " outline " of histology Since each " fact " is stated, as far as possible, in a line of the text, which averages 30–40 lines in each page, about 12,000 " facts " receive mention Can the average student absorb more than a portion of all this ? And which portion ?

Deliberate jettison of all that makes a textbook more than a concatenation of statements may be justified if the abbreviation is a true one, and permits more leisure for mental digestion But if compression merely allows the introduction of further pabulum, the meal becomes indigestible In much medical teaching today, mere instruction predominates and education lags behind It would be harsh to judge it entirely in this light, but the book seems to us to have defects as a sole guide to beginners in histology, however useful it may prove to those who, with a background of understanding, seek to revise its facts

Portal Hypertension

ALAN HENDERSON HUNT, D M, M CHIR, F R C S, surgeon, St Bartholomew's and The Royal Marsden Hospital Edinburgh and London E & S Livingstone 1958 Pp 230 40*s*

IN British surgical literature Jacksonian prize essays form an ancient lineage Mr Hunt's monograph on portal hypertension, which was awarded this prize by the Royal College of Surgeons of England in 1956, now appears in print, and it proves him worthy of his illustrious predecessors The book is essentially a clinical account, based on 250 cases, the largest individual series yet analysed in this country It does more, however, than describe methods and present results it reflects the struggles, failures, and successes which have made the first ten years of operative treatment of portal hypertension one of the most exciting chapters in surgery Its smallness was dictated by the requirements of the prize for which it was submitted, and the author regrets that 75,000 words did not allow him to summarise all recent scientific work on liver disease and hepatic circulation, but he has been outstandingly successful in relating that work to his own clinical experience

His concise yet uncramped style, as well as the soundness of his judgment, will assure for the book a warm welcome not only from specialists but also from general physicians and surgeons, many of whom still regard the surgical treatment of portal hypertension with a mixture of awe and distrust If, after reading these pages, they decide that it is still a highly specialised subject, they will yet have enjoyed and profited by a lucid account of a complex but not uncommon group of illnesses

In common with most workers in America and in this country, Mr Hunt favours shunt operations as the surgical treatment, but he never turns a blind eye to their limitations and dangers Apart from many technical difficulties, patients with severe and even moderately advanced cirrhosis are still beyond surgical help and the emergency treatment of ruptured varices remains controversial and, on the whole, unsatisfactory (George Crile contributes a useful chapter on transœsophageal ligation of varices) Mr Hunt deals with technical matters and alternative operations in a series of appendices from which no detail of practical importance has been omitted, and a series of succinct case-histories complete the work The illustrations are a credit to the writer's technical and clinical team and to his publishers

New Developments in Analytical Psychology (London Routledge & Kegan Paul 1957 Pp 214 25*s*)—This book by Dr Michael Fordham contains nine essays on various topics of analytical psychology The first four, which are the longest, are concerned with biological theory and the concept of archetypes, the archetypes and synchronicity, image and symbol, and the transference As in most Jungian writings, a difficult subject is not simplified for the uninitiated by conciseness or by definition of the ideas considered, but most psychotherapists should glean occasional kernels The last five chapters are concerned with theories of child development, the analysis of the child, and the child-guidance approach to marriage, and are less theoretical in presentation

Hospital Coccal Infections (Association of Clinical Pathologists 1958 Pp 39 3*s* 6*d*)—Last year a symposium on hospital coccal infections was organised by the Association of Clinical Pathologists and the Medical Research Council Committee on Cross-infection in Hospital, and we gave some account of it [1] The papers by the principal speakers have now been published, together with summaries of the discussions, in a booklet, which may be obtained from the Swan Press, Ltd, 20, Bakers Row, Farringdon Road, London, E C 1 The editors are Dr R E O Williams and Dr R A Shooter

New Inventions

THE ST THOMAS'S HOSPITAL NERVE STIMULATOR

IN THE DIAGNOSIS OF PROLONGED APNŒA

UNEXPECTEDLY prolonged response to muscle relaxants has been reported increasingly often in recent years [1–4], and its possible theoretical causes have been outlined [5] One of the principal difficulties facing most anæsthetists is to determine whether the failure of return of full muscle power is due to a central cause affecting the brain (e g, analgesic, anæsthetic, or excess of carbon dioxide), or to peripheral weakness caused by prolongation of the neuromuscular block No ordinary clinical examination can differentiate between these two causes, but electrical stimulation of a peripheral nerve (e g, ulnar) will immediately reveal whether the skeletal musculature is responding to impulses or not, provided the intensity of the stimulus (i e, the current) is sufficient

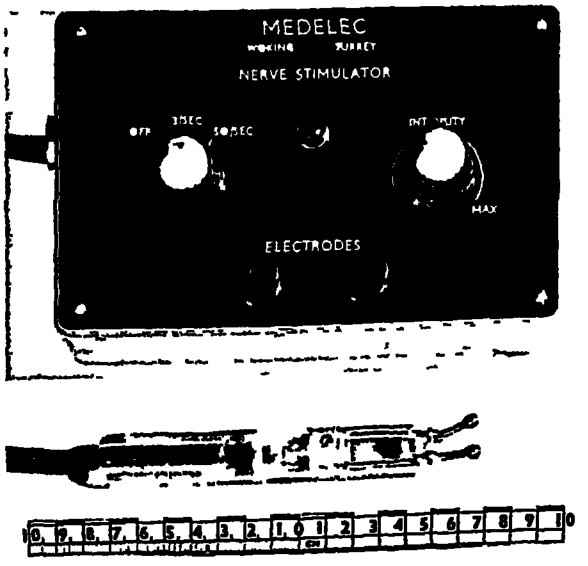

Fig 1.

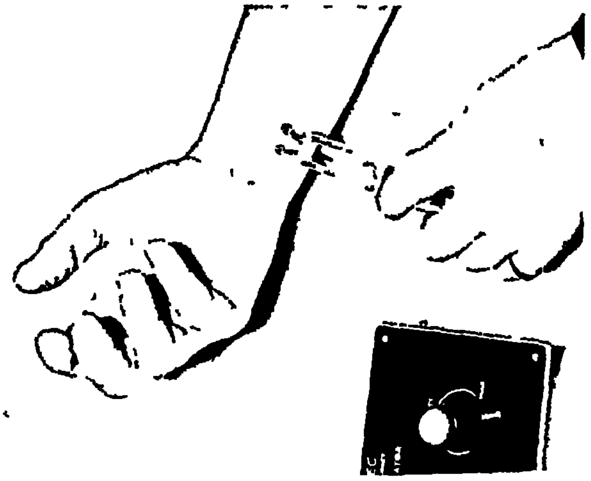

Fig 2

In the past, electrical stimulators have not been readily available, but during the last five years various models have been in use at this hospital for research purposes The present apparatus (fig 1) has been designed for use in the operating theatre and is now produced commercially It is capable of stimulating at either slow rates (twitch—3 per sec) or fast rates (tetanus—50 per sec) In man, ordinary volition uses a rate varying from 30 to 50 per sec according to the force of the muscle contraction The intensity of the stimulus can be altered at will, but in the unconscious subject it is advisable to use the maximum possible to ensure that all the muscle-fibres served by that nerve will contract

In the event of an abnormal response to a muscle relaxant this machine can be used to stimulate the ulnar nerve at the wrist or the elbow (fig 2) Then, if neuromuscular block is present, the 4th and 5th fingers will not move, on the other hand, if normal neuromuscular transmission is present, the typical picture of main-en-griffe will result

We believe this nerve-stimulator will prove very useful to anæsthetists It can be used to study the action of muscle relaxants during routine anæsthesia or (by changing the electrodes) to detect the whereabouts of the facial nerve at operation

Our thanks are due to Dr P Bauwens for his helpful advice

The St Thomas's Hospital Nerve Stimulator can be obtained from Medelec Limited, Woking, Surrey

THE LANCET

LONDON 12 APRIL 1958

Iodine Prophylaxis of Goitre

"ENDEMIC goitre is the easiest known disease to prevent," said MARINE[1] in 1915 This confident remark has been fully justified by subsequent experience The United States, Switzerland, and New Zealand have been using prophylactic iodine for several decades, and goitre has notably declined in all three countries[2] Similar measures have been introduced more recently in Canada, Mexico, Guatemala, Colombia, Peru, Argentina, Paraguay, Sweden, Holland, Poland, Rumania, Yugoslavia, Hungary, Czechoslovakia, Italy, and parts of Australia[2] These measures have been applied with varying degrees of thoroughness, and in most cases too recently for proper assessment of the results Nevertheless it is impressive that so many countries should think it worth taking official action to increase the iodine intake of their inhabitants So far this country has made no attempt to eliminate goitre The iodisation of salt was recommended by a subcommittee of the Medical Research Council in 1944[3], and this recommendation was widely supported[4] In 1950 the Government of the day seemed about to take action,[5] but in the event nothing was done So many other countries are now ahead of us in this simple public-health measure that official inertia is making us look somewhat oldfashioned

We do not know what induced the Government to withdraw its proposed measures for iodising salt, but there seem to be at least three rational grounds for hesitation

One is the possibility that in this country other goitrogenic factors outweigh the effects of iodine deficiency In clinical practice occasional goitres are certainly not due to iodine deficiency—for example, those due to chronic thyroiditis, the goitrogenic drugs, and hereditary causes All these are rare, however, and they are distinguished from ordinary sporadic goitre by their tendency to be associated with hypothyroidism Our diet is unlikely to include significant amounts of goitrogenic substances unless we consistently eat raw turnips[6] or drink milk from cows fed on related cruciferous plants[7], and if such substances were an important constituent of the diet we should expect to encounter hypothyroidism as well as goitre ASTWOOD[6] has pointed out that the thyroid is likely to compensate better for iodine deficiency than for a chemically induced block in thyroxine synthesis The fact that the ordinary goitre is practically never associated with hypothyroidism is indirect evidence that it is caused by iodine deficiency rather than by a positive goitrogen More direct evidence has been provided by BURRELL and FRASER,[8] who have shown that some non-toxic goitres studied in London were unduly avid for radio-iodine but that this avidity could be abolished by brief treatment with small doses of iodide While there is no proof that iodine deficiency is the main factor in the causation of goitre in this country, there is at least no evidence incompatible with that hypothesis

A second possible reason for official hesitation is the argument that goitre in this country is not of sufficient practical importance to warrant action on a national scale In most cases, it may be reasoned, the inconvenience of having a goitre is cosmetic rather than medical Admittedly it has never been proved that the common accompaniments of endemic goitre—cretinism and deaf-mutism—are themselves caused by iodine deficiency, and it is still open to question whether a reduction in the incidence of simple goitre would be associated with a similar diminution in the incidence of toxic goitre and thyroid cancer Yet even in the absence of these complications there are disadvantages about having nodules in one's thyroid In his article at the beginning of this week's issue Mr SELWYN TAYLOR traces the origin of thyroid nodules back to a stage of simple hyperplasia, and it is at this stage (probably about the age of puberty) that we believe goitre to be preventable Once puberty goitre has developed, thyroxine or thyroid extract is a rational, and often an effective, treatment But when nodules are present the surgeon's knife is the only useful therapeutic weapon This is an expensive weapon, involving the cost of perhaps two weeks' stay in hospital as well as that of the operation We have no way of estimating how often this operation is being performed, but the Registrar-General's review of hospital inpatients for 1951 shows that patients with non-toxic goitre comprised nearly 1% of the female non-obstetric admissions to teaching hospitals If most of these admissions could be avoided the reduction in hospital costs, though not spectacular, should at least offset the cost of iodising salt On balance iodine prophylaxis could be expected to pay for itself, and even yield a modest profit to the community

The third, and perhaps most cogent, reason for doubt about the desirability of iodine prophylaxis is disinclination to compel people to eat what experts think is good for them This attitude is by no means wholly irrational, since the conclusions of Science are never final but are merely the best current approximations to truth During the war the fortification of margarine and other foodstuffs with vitamin D appeared, in the light of contemporary knowledge, to be wholly beneficent, but we now know that the addition of this vitamin can easily be overdone and may be a factor in the causation of infantile hypercalcæmia[9] At present the addition of small quantities of iodine to salt seems to be entirely unobjectionable and unlikely to do anyone the slightest harm, but no-one can unreservedly guarantee that this will turn out to be true A deeper, if less rational, objection along the same lines is that further encroachment on the liberty of individuals should be resisted The nature of our complex civilisation demands that we submit to many restrictions on our freedom of action as individuals, but our aim should be to keep these restrictions to the bare minimum necessary for the smooth running of society Hence it seems desirable that, although iodine prophylaxis should be introduced as soon and on as wide a scale as possible, some loophole should be left by which those who wish can avoid receiving iodine From this point of view an excellent vehicle for the distribution of iodine would be salt, as was recommended by the M R C subcommittee, and much technical information has been accumulated about methods of iodising this material [10] What is required is that some 95% of all salt used domestically shall be iodised at the level recommended by the M R C Anyone ordering salt would automatically be given iodised salt unless he specifically asked for non-iodised In this way the majority could be protected against goitre without encroaching on personal liberty TAYLOR reaches a similar conclusion The time has surely come for further thought by the Government

Bleeding Varices

THE treatment of ruptured œsophageal varices may have to be undertaken by comparatively inexperienced surgeons at short notice and under difficult circumstances The coming of blood-banks inspired the first attempts to deal actively with this emergency The dramatic effect of prompt massive transfusion on most forms of acute hæmorrhage encouraged the hope that this would prove the life-saving first-aid treatment of bleeding cirrhotics Such hope was soon dispelled experience showed that transfusion alone did not reduce mortality, and that in at least three different ways it could be a contributory cause of death It first became apparent that dilution of the circulating clotting factors by transfused blood made cirrhotic patients, with their already depleted stores, the least suitable subjects on whom to test an excessive faith in banked blood It was then recognised that hepatic failure, precipitated by large nitrogenous blood-meals, was as potent a cause of death as circulatory collapse from blood-loss itself, and that the greater the amount of blood given, the greater the amount the patient could shed into his gastrointestinal tract Most recently attention has turned to citric-acid intoxication [11]—a real danger when liver function is impaired Blood-transfusion remains an invaluable supportive measure, but complete reliance cannot be placed on it

If the phase of massive transfusions was one of unfulfilled hope, BLAKEMORE hardly exaggerates when he describes the next phase as the "carnage of cirrhotics" [12] It coincided with a tremendous advance in the management of bleeding peptic ulcers—the wider recognition that seemingly moribund patients could be restored to health by judiciously timed operations and by expert perioperative management But the knife, which brought new hope to many ulcer patients, spelt doom to the majority of bleeding cirrhotics they too were operated on for bleeding ulcers, and they died of hepatic failure This era left the bleeding-ulcer majority deeply indebted to the hapless minority of bleeding cirrhotics, it ended not with dramatic advances in surgical technique but with the growing realisation that cirrhotics can ill withstand even the best of surgery In at least 70% of hæmatemeses a bleeding ulcer can be diagnosed with fair certainty, but if bleeding cirrhotics are to be given a fair deal, the remaining 30% should be treated (until a diagnosis is clearly established) as potential cases of ruptured varices This demands an entirely different therapeutic approach In the potential cirrhotic the primary aim is not to replace but to stop the blood-loss, and laparotomy is not a valid diagnostic procedure

Differential balloon-tamponade, which serves the dual purpose of diagnosis and treatment,[12-14] has been a real advance in the management of these cases

It is carried out with a specially designed three-lumened tube, equipped with a sausage-shaped œsophageal balloon and a spherical gastric balloon After accurate positioning of the œsophageal balloon by preliminary gastric inflation, air is slowly introduced into the naso-œsophageal tube The distending balloon in the œsophagus encompasses the varices above the cardia, and when the pressure inside it (measured by a built-in mercury manometer) rises above the patient's portal pressure, bleeding ceases BLAKEMORE [12] rightly insists that the balloon used should be specially designed and tested for this purpose

If inflation of the œsophageal balloon does not arrest the bleeding—and this can be verified by aspirating through the nasogastric tube—the gastric balloon must be inflated As much as 400 c cm of air may have to be introduced into this stouter bag, and an upward pull of 2 lb is usually needed to compress effectively the stomach against the diaphragm

If such traction-tamponade does not control the bleeding, it is reasonable to assume that the bleeding-point lies distal to the proximal half of the stomach—probably in an ulcer crater—and some surgeons would attempt to localise it by injecting small amounts of barium into the feeding tube If the bleeding is arrested, a ruptured varix in the upper stomach is the likeliest diagnosis Unfortunately such a finding commits the surgeon to almost immediate operation Not only is compression of the proximal stomach for more than a few hours intolerable to the patient it also leads to rapid deterioration of the gastric mucosa, and, often within twenty-four hours, to ulceration and gangrene It is true that only about 10% of ruptured varices are on the gastric side of the cardia It is also true that the outlook for these patients is poor from the start, and that many have to be operated on as a last desperate measure Traction-tamponade itself, however, makes laparotomy imperative, whereas conservative measures alone—skilled sedation, carefully regulated drip-transfusion, and prophylaxis of liver failure—occasionally tide patients over the acute episode and allow the surgeon to intervene at a more opportune moment

[12] Blakemore, A H *in* Current Surgical Management (edited by J H Mulholland, E H Ellison, and S E Friesen) Philadelphia, 1957

[13] Sengstaken, R W, Blakemore, A H *Ann Surg* 1950, 131, 781

[14] Boerema, I *Congr int Gastroent* Paris, 1954 See also *Lancet*, March 29, 1958, p 681

In contrast to traction-tamponade of the stomach, œsophageal tamponade can be maintained for three or four days if necessary Continued distension of the lower gullet is very unpleasant, but it is rarely intolerable, and nasal ulceration and necrosis can usually be prevented by nursing care and antibiotics There is rarely justification for rushing unprepared into operation on the ground that œsophageal tamponade can be maintained no longer Unfortunately, often what is loosely described (and justly decried) as "œsophageal" tamponade is, in fact, half-hearted traction-tamponade on the stomach It is easy to control bleeding from a ruptured œsophageal varix by compressing its feeding vessel in the upper stomach—and when some improvised contraption is used this is what usually happens—but such a manœuvre is both unnecessary and unpleasant When the varices are in the œsophagus, œsophageal balloon-tamponade properly performed will always provide at least a breathing-space for improving the patient's general condition and summoning expert surgical help

Linton and Ellis [15] have found that it is best to prepare patients for operation as soon as the hæmorrhage is controlled These workers reported 20 cases in which they had performed transthoracic transœsophageal ligation of the bleeding varices either with a view to later shunt operation or as a definitive measure 2 patients died as a direct outcome of the operation, and 3 succumbed to liver failure or recurrent bleeding before a shunt procedure could be done, but in the remaining 15 it was possible to construct, after varying intervals, a portocaval or a lienorenal shunt Transœsophageal ligation of the bleeding varices has the supreme merits of comparative safety and simplicity [16-18], but usually it is of no more than temporary benefit. Crile [19] has achieved some good long-term results in patients with extrahepatic blocks [19], but Linton [20] found that in more than a third of cirrhotics the bleeding recurred in a few weeks or months In this country Tanner [21] devised an operation in which the mid-stomach was transected and resutured after division of all the vasa brevia and of all the branches of the left gastric vein which drained the proximal half Unfortunately, several patients had recurrent bleeds, and, though postmortem injection studies showed no appreciable flow across the gastric suture-line, anastomotic branches between the œsophageal and phrenic veins had apparently maintained a dangerously high pressure in the varices This led Tanner to devise a subcardiac porto-azygos disconnection [22] By an abdominothoracic approach he frees the lowest five centimetres of the œsophagus and the uppermost five centimetres of the lesser and greater curves of the stomach from all external vascular connections, the stomach is then completely transected and resutured five centimetres below the cardia, leaving just enough blood-supply from the œsophagus to nourish the small upper gastric segment Tanner [23] reported that in each of 11 cases of acutely bleeding œsophageal varices this operation arrested the bleeding, but some months later 2 patients bled again, and a further patient succumbed to hæmorrhage from gastric ulceration at the suture-line He also performed the operation in many cases as an interval procedure, with excellent long-term effects This is very encouraging, but post-vagotomy stasis is an almost inevitable sequel to the operation, and, though a few days' gastric suction are an adequate countermeasure in most cases, a second-stage pyloroplasty had to be performed in 2 of Tanner's patients Hunt [18] points out that the operation can be extremely difficult, and he suggests that it is less likely to succeed in cases of cirrhosis than in cases of extrahepatic obstruction

Of the other possible operations, more or less extensive gastric and gastroœsophageal resections, pioneered in America by Phemister and Humphries,[24] may gain a place in the emergency as well as in the interval treatment of ruptured varices [25, 26] Hepatic-artery ligation,[27] though it cannot be recommended in its present form,[28] may yet emerge from obscurity disguised as "portalisation of the artery" [29] Splenectomy still has a few indications [18] and a few able if cautious advocates [30] Shunt procedures,[31-38] now widely regarded as the surgical treatment of choice, have already been performed for acute hæmorrhage O'Sullivan and Payne [39] reported 9 cases submitted to this operation as emergencies 3 died in the immediate postoperative phase, and 3 died later from liver failure, but none of the 6 who survived operation bled again "Arterialisation" of the liver may further widen the scope of shunt operations [18, 40-43] The threat of hepatic failure is at present the most stringent limiting factor in the selection of patients for operation; and, even though few patients with advanced cirrhosis are selected, it remains by far the commonest cause of postoperative death "Hepatic arterialisation' aims at preventing this complication Theoretically it can be achieved by connecting the hepatic end of the divided portal vein to the proximal end of a divided and dispensable artery of the region But no such procedure has yet graduated from the experimental class—and even at that level results are not wholly encouraging [44] Nevertheless further progress may be along these lines

Pituitary Tumours

Of the many pituitary tumours most are adenomas, and some are Rathke pouch tumours—otherwise called craniopharyngiomas, indicating their origin in fragments of the embryonic evagination of the roof of the mouth which becomes the adenohypophysis. Primary malignant lesions are rare. The adenomas usually present in adult life, radiographs show much ballooning of the sella turcica and erosion of the clinoid processes. The Rathke pouch tumours often give symptoms in childhood, they are extrasellar more often than intrasellar, with a typical radiographic picture of calcification above a much less expanded pituitary fossa. Any pituitary tumour may threaten life and vision by pressing on nervous tissue or by causing internal hydrocephalus. Symptoms include headache, nausea, vomiting, blurred vision (sometimes transient or uniocular), and bitemporal or other scotomas, less common are epilepsy, trigeminal pain (not always due to malignant lesions), hemiparesis, diplopia, ophthalmoplegia, and papillœdema. Involvement of the hypothalamus may give rise to obesity, thirst, polyuria, thermal disturbances, and somnolence.

Such dramatic and urgent events may obscure the fact that pituitary tumours usually have an endocrine as well as a neurological aspect, and that the endocrine effects often long precede the neurological. Jefferson[1] studied 131 cases of chromophobe adenoma and 57 cases of Rathke pouch tumour. In half the male patients with chromophobe adenoma there was a history of sparseness of facial hair, sometimes with definite lack of body hair, usually starting in the late 'teens or early twenties, and preceding visual symptoms by as much as 45 years. The first symptom in half the female patients was upset in the menstrual rhythm, followed after a shorter interval ($5^1/_2$ years on average) by visual symptoms. It has long been accepted that chromophobe adenomas (in contrast to the hypersecreting eosinophilic adenomas, which give increased somatic growth, and the very rare basophilic adenomas) do not contain active hormones but tend to cause hypopituitarism by crowding out the other cellular elements of the hypophysis. But might not the chromophobe adenoma be regarded as a group of cells which multiply in an effort to compensate for some metabolic abnormality?[1] Russfield and her colleagues[2] think so. They believe that the primary defect may be atrophy and insufficiency of the gonads or thyroid, that this eventually stimulates the pituitary to hyperplasia and neoplasia, that some "chromophobe adenomas" do secrete hormones which can cause hyperplasia of the adrenal glands and other "target organs", indeed that the difference between the tumours of acromegalic and non-acromegalic patients is often quantitative rather than qualitative. Be that as it may, it is beyond question that the various types of pituitary tumour can destroy the pituitary, and so lead to atrophy of the adrenals, thyroid, gonads, and genital tract, and to the clinical syndrome of severe hypopituitarism.[3] It seems likely, too, that pituitary insufficiency from pituitary tumours is incomplete more often than complete, and the incomplete form can be a more elusive diagnostic problem. At the Mayo Clinic Troen and Rynearson[4] found evidence of 41 mild and 25 severe cases of hypopituitarism in 153 patients before operation. Endocrine insufficiency is an important source of ill health in such cases and demands treatment with, say, cortisone, testosterone, or thyroid, or combinations of these, according to the needs disclosed by clinical and laboratory assessment. Conversely, the finding of an endocrine disorder may demand a radiograph of the skull, since there may be no other clinical pointer to a pituitary tumour.

Patients with untreated hypopituitarism are liable to attacks of mental confusion or coma, often associated with bizarre neurological signs. The attacks may be precipitated by intracranial operations, hæmorrhage into a pituitary tumour, infections, drugs, or anæsthesia, and be associated with hypoglycæmia, or sodium depletion, or water retention, or cerebral anoxia.[5] Severe endocrine failure, especially of the adrenal cortex, seems to be the most important common factor in these catastrophes, and in the presence of a big pituitary tumour there is real danger that such attacks be wrongly attributed to, say, internal hydrocephalus or pressure on vital cerebral structures, and so lives may be lost for want of cortisone therapy. Jefferson,[6] in a retrospective study covering periods before the introduction of modern endocrine treatment, considered that of 61 deaths in cases of pituitary tumour 26 were due wholly or partly to endocrine failure. After operations on the pituitary, complications are commoner in patients with hypopituitarism, and their incidence is reduced in these patients by giving cortisone before operation.[4] Although many postoperative complications and deaths are not readily explained by endocrine disorder,[4 5] cortisone reduces the general mortality from operations on pituitary tumours, irrespective of the preoperative and postoperative endocrine status.[4]

In the treatment of the tumour mass, operation is rarely required in the absence of visual disturbance, but it is imperative if there are urgent pressure symptoms. With Rathke pouch tumours, deep X-ray therapy is unsatisfactory and operation risky. There is less certainty about the management of pituitary adenomas with mild to moderate visual loss. At the Lahey Clinic[7] in 1932–49, 89 patients were treated for visual loss by irradiation only, but of this number 56 were operated on subsequently because vision was not held at a useful level, indeed, the vision of some was so greatly reduced that they were not benefited by surgical removal of their adenomas. Since 1950 a method has been used whereby a tumour dose of 4000r can be delivered with safety. Of 66 patients with visual loss so treated in

1950–55, only 8 have required operation. These preliminary results are encouraging, but during therapy there is need for the most careful evaluation of visual tests, for which the neurosurgeon should be responsible[8] Patients with pituitary adenomas who are correctly treated can survive a long time[1] These cases are well worth the thoughtful care which must be given to their diagnosis and management.

Annotations

THE EVOLUTION OF VISION

WHEN Lister returned from Scotland, surgical London flocked to his first lecture to hear the latest news of his technique, but he had been interested in the curdling of milk, and told the audience, instead, about the *Bacillus lactis* that he had discovered Introducing his Lister oration on March 28 with this story, Sir Stewart Duke-Elder elected to talk, not of any detail of eye surgery, but of the Emergence of Vision in the Animal World He pointed out that whereas most lower animals depend largely on other senses, and their brains (" nose-brains ") are largely devoted to smell, the human brain is an " eye-brain ", with its receptive area behind, large association areas, and centres for control and coordination further forward

Sensitivity to light is first manifest as a motor reaction An amœba will move away from light as it will from any other noxious stimulus, some insects move not directly towards or away from a light but in a direction at a constant angle to it By this means an ant, moving at a constant angle to the sun's rays, can find its way back to its home, but if it is imprisoned in the dark while the sun moves through an arc, when released it will set off in the wrong direction Moreover, if the source of light is, unlike the sun, near by, moving at a constant angle will involve moving in a spiral, that is why the moth flies to its death in a candle flame Bees can orient themselves by the sun, but can make a correction for the time of day, and so can birds Manx shearwater released in America flew, lost, in any direction on an overcast day, on a sunny day they oriented themselves correctly in 40 seconds, and flew across the Atlantic, each to its own particular burrow off the west coast of England

These reactions are unlikely to involve visual *perceptions* Plants too can react to light—*Hedysarum girans* nods to a passing cloud—and machines can follow a torch In animals purposeful appreciation can reverse the automatism of a response thus a cockroach, which normally avoids light, can be taught to approach it if there is a dark shelter underneath The first animal to show such intelligent appreciation is the earthworm, which has many light-sensitive cells, and normally approaches a dim light and avoids a bright one, but it can be conditioned to respond in other ways Thus vision for the first time is associated with awareness the animal can see, though it cannot form an image of anything Appreciation of movement in the outside world is evident in the molluscs any movement causes the protrusion of the organs of chemical and tactile sense But sensitivity to movement is important in an animal as high as the rabbit, which will run into a stationary man Form vision appears in cephalopods—an octopus can distinguish between vertical and horizontal lines—and colour vision in certain insects, though it is important only in fishes, birds, and primates

Development of vision depends on environment In deep-sea fishes, which live in darkness, it is lost, in small mammals, such as the dog and cat, living near the ground, it is less important than tactile and olfactory sensation The highest development has come in certain fishes (living in a three-dimensional world) and more particularly in birds and arboreal creatures—tree-snakes, tree-shrews, and primates The swaying habitat of branches necessitated the development of prehensile limbs and fine stereoscopic vision, moreover, "the security of the tree-tops allowed an escape from the urgent fears of life on the ground with its teeming population of predators, so that the senses, not constantly alert for danger, turned to other things" New explorations by hand and eye gave rise to new associations, curiosity, and inventiveness—the foundation for the intellectual supremacy of man

A chimpanzee, unlike lower mammals, will amuse himself visually—by looking at the world upside down or through a hole, or even with a kaleidoscope This is the first indication, says Sir Stewart, " that vision has become elevated from the level of biological usefulness to approach that of æstheticism " In evolution, he says, there are stages when something new appears different from its constituent parts, thus the molecule differs from its atoms, and other stages are marked by the emergence of life and of consciousness In the evolution of vision the first stage is that of the motor reaction, the second that of perceptual vision, which emerges in the earthworm with a brain-ganglion, for it needs central nervous organisation The third emergent is imaginative vision, exploratory and creative, dependent on the development of forebrain and association areas

We know that animals see, but not what they see Analysis of our own perceptions is hard, analysis of those of dumb creatures is impossible Sensations can be appreciated and interpreted only through our perceptions, we know of no corresponding higher stage for the interpretation of our perceptions But the brain of a bee, which can correct for changes in the sun's position with time, is only $^{1}/_{10}$ in across, the brain of man is vastly bigger, and may expand further New capacities and understandings may well emerge—given time, for the apes threw sticks and stones, and we throw atom bombs

NOMENCLATURE OF PATHOGENIC FUNGI

THE former unsatisfactory state of the nomenclature of fungi pathogenic to man was due, in some measure, to inadequate description of newly named species, which led to the same species being renamed from time to time by different authors, also to the tendency to variation inherent in many fungi, the unidentified variant often being accorded specific rank These faults gave rise to multiplication of names, and in a work on pathogenic fungi published twenty years ago some 746 " species " were recorded Since then a new and more scientific interest in fungus diseases, particularly the systemic infections, has been aroused by the discovery of their widespread distribution in some countries, mainly through mass radiography of the chest and routine testing for specific cutaneous sensitivity to fungus antigens

Through the work of the Committee on Medical and Veterinary Mycopathology of the International Association of Microbiologists, international agreement on the

8 Ray B S *ibid* p 5

use of recommended names has been secured to a great extent, and revised nomenclature is in general use in the countries of North and South America and the British Commonwealth, and to a lesser degree in some European countries. To ensure uniformity and avoid confusion, authors of papers on fungus diseases and medical mycology should consult the revised authoritative list of names of pathogenic fungi and fungus diseases.[1]

THE UNHEALTHY AREAS

EVER since Farr, the General Register Office has been disturbed by the striking disparities in death-rates between different areas in England and Wales. Such disparities are important for two reasons: first, as a spur to local public-health action, and secondly as suggestive clues in epidemiological studies of disease causation. In this respect, the analysis of mortality by geography supplements its dissection by occupation, and by the publication of the volume on area mortality,[2] the Registrar General completes the major studies based on the national experience during the years around the 1951 Census.

The geographical distribution of mortality in England and Wales follows a set pattern with higher death-rates in the north and west. In the north-west region both male and female mortality-rates were at least 10% above the national average, and an excessive infant mortality there completes the evidence of an adverse social environment. As the Registrar General remarks, climate in itself is unlikely to be of major importance. Indeed a detailed survey of the death-rates by cause in different areas strongly suggests the relevance of atmospheric pollution. Bronchitis, for example, bears much more heavily on both sides in the north-western region, and there is a marked gradient in mortality from the standardised mortality ratios for both sexes. Male mortality, for example, rises from 62% of the national average in the rural districts to 139% in the provincial conurbations. Greater London, with a rate of 123 for male and 117 for females, is still seriously afflicted, particularly in districts such as Shoreditch and Southwark where the smoke pall lies heavy.

Some of the social and selective factors which determine the incidence of disease and death are apparent in the experience of the county boroughs largely devoted to major industries where either men or men and women may be employed. In cotton towns such as Oldham, the death-rate among women is 23% above the national average. Some of this excess can be explained by death-rates from bronchitis more than twice the rate for women in the country as a whole, and it is possible that the effects of employment outside the home are superimposed on the results of a smoky and crowded domestic environment. It is perhaps significant that in towns such as Oldham and Rochdale the infant-mortality rate is among the highest in the country.

The men of the mining areas of South Wales have the high mortality from respiratory diseases usually associated with this occupation, but the women of the same areas shared this excess of mortality. In Merthyr Tydfil, for example, the death-rate among females was 23% above the national average. These findings emphasise how death-rates by occupation must be looked at against the perspective of the mortality patterns of the areas where major industry is sited. The interpretation of death-rates whether by occupation or area also depends on the community history of the ebb and flow of migration in step with the expansion and contraction of the basic industry on which depends the inhabitants' standard of life. The draining of the fittest and most vigorous men away from derelict areas, agricultural or industrial, has always been a melancholy spectacle, and its end-results are evident in the vital statistics of the residual population. Whether because of similar migration of the fit single women, or through some process of assortive mating by emigrant males, similar trends are evident in the mortality of the women in these areas.

Any realistic assessment of this latest publication by the General Register Office will thus require the most careful partitioning of blame for excessive mortality between occupational, environmental, and socio-economic factors. There is, however, in these tables of assembled facts no reason for complacency about the health of many of our most important areas and much to stimulate thought, research, and action.

CLOSTRIDIUM WELCHII FOOD-POISONING FROM COLD CHICKEN

COLD chicken is a traditional item in the diet of the convalescent, and indeed of any patient whose digestion is considered unequal to the rigours of ordinary diet. For its preparation a big hospital may have to boil some twenty or more fowls at a time. These are usually cooked in a large boiler in water for some two to three hours, after which they are removed from the boiler and allowed to cool at room temperature before being refrigerated. This process is not without risks of bacterial contamination, which may lead to food-poisoning. In the United States McClung[1] reported outbreaks, among the customers of a large public cafeteria, of *Clostridium welchii* food-poisoning conveyed by chicken cooked one day and served the next. On page 787 of this issue, Dr McNicol and Miss McKillop show that this kind of food-poisoning may also strike hospital patients. As they say, the victims are usually those given light diet. Many of these may suffer severely, and some, especially among those recovering from major abdominal operations, may die from the infection, which does not usually cause a very serious illness in a healthy adult.

In hospitals generally, some of the unexplained outbreaks termed "hospital diarrhœa" might be proved to be due to *Cl. welchii* conveyed by cold chicken if only the appropriate investigations were made. There is nothing technically difficult about isolating and identifying *Cl. welchii*, the hard thing is to persuade doctors and nurses that they should demand a proper investigation of all cases of diarrhœa in hospital. Diarrhœa that is relatively mild and brief is often ignored, or the patient is assured that he has probably had a little too much aperient. Where any bacteriological examination of an outbreak is undertaken, usually only one or two samples of stool are submitted from the few patients whose diarrhœa persists rather longer than that of the others. Salmonellas and shigellas are not found, *Cl. welchii*, even if it is found, is perhaps dismissed as of doubtful significance because most humans carry it in the intestine, and so yet another incident is unhelpfully diagnosed as "hospital diarrhœa." In the investigation of cases of diarrhœa in a hospital ward there is need (as in McNicol and McKillop's experience) for a full history and a diligent search for an article of food common to all who have had even minor symptoms Cold chicken is so acceptable a delicacy that it is seldom that any is left over to be examined, instead, the remainder will probably have been shared among some for whom it was not primarily intended Examination of these also, whether they have symptoms or not, is a necessary and often very helpful part of the investigation For physical as well as other reasons, however, it often proves difficult to secure for laboratory examination samples of stool from all at risk

[1] McClung, L. S. *J. Bact.* 1945, 50, 229.

Chiefs of wards do not always realise that, for many reasons, the reporting and investigation of hospital diarrhœa by their staffs is commonly less than adequate McNicol and McKillop emphasise that they have gained something from the use of rectal swabs to collect the samples they needed Some evidence reported by Hobbs et al[2] suggests that examination of rectal swabs for *Cl welchii* may be less certain of giving a positive result than examination of a sample of stool Against this, however, use of the rectal swab makes it possible to ensure that a sample is secured for examination from all at risk, and the finding of many *Cl welchii* in the fæces of an abnormally high proportion of those at risk often constitutes the first real evidence that this form of food-poisoning is the cause of an outbreak of diarrhœa

In such outbreaks the *Cl welchii* isolated from the intestines of the patients is often in heat-resistant form (withstanding 100°C for an hour or more) and is often non-hæmolytic on horse-blood agar Sometimes typing of such strains by agglutinating antisera reinforces the probability of a common source of infection,[2-4] but many strains are still untypable Moreover it is untrue that *Cl welchii* food-poisoning is caused only by heat-resistant, non-hæmolytic strains Nor can it be assumed that the causal organisms, even when they are fully heat-resistant, were necessarily present in the food before cooking Hobbs et al,[2] for example, refer to two outbreaks caused by typical hæmolytic strains that were only feebly resistant to heat Strains of *Cl welchii* of all kinds are very widely distributed in dust, including the dust of hospital kitchens McNicol and McKillop suggest that boiled fowls sitting in their own broth in a large container in a hospital kitchen are often exposed to invasion by dust-borne *Cl welchii*, for which boiled fowls in broth is an excellent medium This explanation agrees with that of McClung,[1] who emphasised that the cause of trouble in the outbreaks he reported was not lack of refrigeration but failure of the pans of food to cool quickly enough to a safe temperature Dische and Elek[5] showed that not all strains of *Cl welchii* cause food-poisoning, otherwise we might experience much more trouble of this kind

McNicol and McKillop suggest two ways of reducing the risk both from heat-resistant *Cl welchii* already in the chickens and able to survive cooking and from strains that might gain access after cooking From both these sources the risk could be curtailed and perhaps removed by cooking the chickens in a pressure-cooker and keeping them sterile by not opening the cooker until the chickens are to be served If this procedure is unacceptable, the cooked birds should certainly be taken from the broth as soon as possible after boiling and cooled in a place protected from dust—preferably being put into a refrigerator at the first possible moment To ensure that they cool quickly they should be well separated from each other—on a shallow tray, for example, as recommended by Norval and Collee,[6] who found that slowly cooled steak pies were admirable culture media for *Cl welchii* If, through forgetfulness or unawareness of risk, the birds are allowed to remain overnight in broth unprotected from dust and in a mass which cools slowly, diarrhœa may result

ANÆSTHESIA IN THE NEWBORN

ANÆSTHESIA for major operations in the newborn is associated with special difficulties Rees[7] believes that, the respiratory system being relatively immature, controlled ventilation at a high rate is indicated, and that this can be carried out satisfactorily provided that blood-loss is made good and a muscle relaxant is used The choice of relaxant is important, since the newborn child is sensitive to agents, such as *d*-tubocurarine chloride, that do not depolarise, yet relatively resistant to those that do[8] Suxamethonium is thus the agent of choice, but, as Rees points out, sensitivity to agents that do not depolarise may go hand in hand with a dual response to those that do, and long-continued administration of suxamethonium may be followed by depressed respiration This depression can be offset by neostigmine, but it is best avoided or at least decreased by carefully regulating the total dose of suxamethonium In adults the easiest way to keep the blood-suxamethonium at the minimum necessary level over a long period is to administer it by continuous intravenous infusion, but in a child this would require infusion of far too great a volume of fluid, and intermittent injection is essential This, by contrast with continuous infusion, is likely to call for a far greater total amount of suxamethonium, and small and frequent doses should be given in order, as far as possible, to mimic continuous administration

Intubation of the trachea is essential not only because of its importance for controlled ventilation but also because of the difficulty otherwise of maintaining a satisfactory airway Passage of the tube may be technically difficult when congenital abnormalities are present—especially micrognathia, in which the tongue is held back on the posterior pharyngeal wall by the underdeveloped lower jaw, and subglottic stenosis, which cannot always be discovered before intubation is attempted Since such factors are likely to prolong the act of intubation, Rees recommends that this should be carried out before anæsthesia is induced and without the aid of a muscle relaxant Thus, moreover, the danger that vomit may be aspirated is curtailed

Rees has calculated, on the basis of figures from the Liverpool area, that in the United Kingdom each year some 2000 newborn babies may need major operations—which suggests that these and other anæsthetic problems in the newborn are common enough to merit special study

DR ROBERT PLATT has been re-elected president of the Royal College of Physicians of London for the coming year

MR E M T FIRTH has been appointed Registrar General in succession to Sir George North, who is to retire on April 30 Mr Firth has been under-secretary and director of establishments at the Ministry of Health since 1947

RESPONSIBILITIES IN CEREBRAL PALSY

Individuals, Society, and Voluntary Agencies

E ELLIS
M D Cantab , D C H
MEDICAL DIRECTOR OF THE PERCY HEDLEY SCHOOL FOR SPASTIC CHILDREN, NEWCASTLE UPON TYNE

CEREBRAL palsy is not a new discovery, but it has aroused general interest in this country only in the past twelve years In the north of England fresh impetus was given to the study of cerebral palsy when a special school for affected children was opened in Newcastle upon Tyne in 1953 The management committee of this school appointed a medical director to

(a) Maintain an up-to-date register of children with cerebral palsy living in the five northern counties, from which it would be possible to determine the nature of the problems which cerebral palsy presents in this area, the number of children affected, and the facilities which should be provided for their care, education, and treatment,

(b) Establish an outpatient clinic for children with cerebral palsy where, in addition to the clinical examination of the child, an assessment could be made of the domestic and social circumstances in which the child lived, and the adjustment of the child and other members of his family to their circumstances,

(c) Keep the work of the school and the clinic constantly under review, so that the emphasis of the work could be altered to meet the needs of the five northern counties

This paper, therefore, is based on experience gained during the past five years in the north of England

There is some evidence that the incidence of cerebral palsy in this country has risen in recent years Ingram (1955) has suggested that the higher incidence of cerebral palsy which he found in Edinburgh in the period 1944–49, compared with the period 1938–43, was due not only to improvements in infant care in the neonatal period but also to survival of infants after illnesses which would formerly have been fatal The infant-mortality rate in England and Wales fell steadily from 150 per 1000 in 1900 to 23 in 1957 It seems inevitable that, along with this tremendous saving of infant life, a number of brain-injured children, who would previously have died, are now helped to survive, and that cerebral palsy is part of the price which the community must pay for the considerable improvements which have taken place in obstetric and pædiatric practice in the past fifty years

It is now generally agreed that cerebral palsy is a comprehensive term, covering a large number of conditions, with a variety of ætiological factors Knowledge about these factors has increased very slowly in the past century, and it seems unlikely that any spectacular advance will result from further retrospective studies Useful information may, however, be accumulated from long-term prospective studies Meanwhile, pressing problems are presented by those who suffer from cerebral palsy, and its management calls for careful attention If cerebral palsy is part of the price which the community must pay for improved obstetric and pædiatric care, how must the price be paid ?

Individuals

Parents

Cerebral palsy implies delayed motor development, which in most children is first recognised by the parents The more severely affected the child, the earlier is the abnormality noticed As it is usually the parents who take their child to their doctor for advice, the parents may be considered the first link in the chain of management

It is the duty of the doctor to explain the significance of the diagnosis to the parents and to advise them about the management of the condition It remains the parents' responsibility, aided by this advice, to care for their child at home day by day and year by year Theirs indeed is often a hard task They must maintain their understanding and their interest, in the face of an increasing physical burden and of their anxieties for the future They will always have to accept more than normal responsibility for their child If they can do so, they can help him to make the most of his disabilities If they are overwhelmed by their burden, if they neglect or abandon their child, he is indeed " deprived ", not only of a normal home life, but of the chance of ever living outside the artificial atmosphere of an institution It may well be said that the most important factor in the life of a young disabled child is the attitude of his parents to his disability

Doctor

The doctor must help the parents to play their most important role by bringing them gradually to understand, and later to accept, the full significance of the diagnosis He must always be available to give explanation and advice as each new situation is encountered

A hospital specialist who has a particular interest in cerebral palsy is usually the doctor who should give most of the initial explanation and advice He, too, may best be able to advise about treatment, while at a later stage a school medical officer can help with educational difficulties The advice of several specialists may be needed, about the child's vision, his hearing, or his intelligence, but for most parents their family doctor, because he is the doctor who knows the family best, is the doctor best qualified to give them continuing help, and he should remain as a link, interpreting the experts to his patients

Therapist

As interest in cerebral palsy becomes widespread, the diagnosis can be made at an increasingly early age As knowledge slowly accumulates, it is becoming accepted that a large proportion of those with cerebral palsy have only limited intelligence The challenge to the therapist at the moment is to find a way of helping young children and backward children, as well as older children of normal intelligence

The word treatment, applied to cerebral palsy, is potentially dangerous, because to many parents treatment implies a prospect of cure, and this blinds them to the incurable nature of the condition Therapists who wish to help children with cerebral palsy must have a clear understanding of the way in which a normal infant develops Only then will they be able to recognise abnormal development The study of the normal infant should lead on to a study of the abnormal movements in children with cerebral palsy The mechanisms which control these abnormal movements are set below the cortical level These mechanisms can therefore be used or modified by the therapist in young children, or mentally defective children, who are unable to cooperate, but for the achievement of voluntary control of fine or complicated movements intelligent cooperation by the patient is necessary

Therapists must not concentrate on motor development alone Because children with cerebral palsy move very little, their knowledge of their environment is limited

Sensation, or sensory perception, may be abnormal, so that the young child lacks the normal stimuli which are necessary for normal intellectual development Whether this delay by deprivation can ever subsequently be corrected remains in doubt, but it seems logical to widen the sensory experience of young children with cerebral palsy, not only by encouraging normal movements, but by using suitable toys and materials such as dough, plasticine, sand, and water At this point the therapist is trespassing on the preserves of the nursery-school teacher, but instead of regarding the two individuals as having separate functions, it would be preferable to regard them both as encouraging a single process of continuing motor and sensory development This approach to the management of cerebral palsy, which is strange to many therapists trained by conventional methods, calls for much observation and study, but it may yield results in cerebral palsy of all grades of severity and at all ages

It would be unfortunate indeed if, as the result of so much specialisation, the therapists came to regard themselves as experts essential for treatment It is not uncommon for children to be brought frequently from distances to attend crowded treatment departments, where their mothers are given a seat in a waiting-room while the child receives the expert attention of the therapist in an inner room This method of treatment may be the result of a constant urge to do something for the child In many cases it may meet to some extent the emotional needs of the parents, but far better that the time should be spent with the mother or father explaining the ways in which they can modify their child's development at home By teaching the parents in this way the therapists can ensure daily help for the child By taking the parents into her confidence the therapist can lessen their sense of frustration and can substitute for it a sense of achievement and pride in their child's progress

Society

Welfare Services

One of the results of cerebral palsy is social isolation The affected child is prevented by his disabilities from making normal contacts with other children and is thrown back upon the resources of his parents and his family Because their child is so abnormally dependent upon them, the parents themselves become socially isolated Recreation away from their home, either during the evenings or at holiday times, may be impossible for them This is a particular strain on the mother whose daily routine ties her to her home

The presence within a family of a severely disabled child may place a great strain upon the bonds which unite the family If these children are to benefit from home life, the break-up of their families must be prevented Even in the welfare state it is impossible to find for the disabled child an adequate substitute for home care

Cerebral palsy must therefore be recognised, and accepted by the community, as a social problem, so that appropriate welfare services, such as social clubs and holiday homes for affected children, and home helps or sitters-in for their parents, can be provided to meet the real needs of these children and their families The alternative to providing these welfare services is to provide a series of residential nurseries, residential schools, and institutions, where the patient can live from the time in infancy when the diagnosis is made until the day in adult life when he dies This policy of segregation—of institutional care from the cradle to the grave—is not only economically unsound, but also emotionally and psychologically wrong for the child, his parents, and the community in which they live

Schools, Occupation Centres, and Institutions

To fit children with such a wide variety of motor, sensory, and intellectual disabilities into any educational system, it is clear that a wide variety of schools is needed The following type of provision was made in 1953 and 1954 for the 133 children of school age with cerebral palsy who lived in three representative local-authority areas in the north of England

Type of provision	*No of children*
At home	24 (*18%*)
Home tuition	4 (*3%*)
Normal school or open-air school	70 (*53%*)
School for the educationally subnormal	3 (*2%*)
Special school for children with cerebral palsy	17 (*13%*)
Private school	2 (*2%*)
Occupation centre	3 (*2%*)
Institution	10 (*7%*)
Total	133

53% were attending normal schools or open-air schools It may be argued that this is not an unreasonable figure, bearing in mind the fact that over half of all cerebral palsied children have only a mild motor disability If a child with a physical handicap can manage, and benefit from education, at a normal school, he would better do so than be admitted to a special school where he would be mixing with children more severely handicapped than himself Yet subsequent experience suggests that about a third of those children with cerebral palsy who were attending normal schools or open-air schools had specific learning difficulties or were so backward that they needed more individual help than their teachers could afford to give them

Only 2% of the 133 children of school age were attending a school for educationally subnormal children There is in the northern region, as throughout the rest of the country, a shortage of accommodation of all kinds for backward children, in special schools for the educationally subnormal, in occupation centres, and in institutions This shortage is a particular hardship to the cerebral-palsy population, because it includes a relatively larger number of backward children than does the rest of the population

Below is an estimate, based on the combination of motor disability and intelligence of the 133 children who lived in the three representative local-authority areas, of the provision needed for children of school age with cerebral palsy

	Percentage
Normal school or school for physically handicapped pupils	30
Class or school for the educationally subnormal	24
Occupation centre	8
Institution	8
Special school for children with cerebral palsy	12
Special occupation centre for children with cerebral palsy	18
Total	100

Special provision should be made for two types of cerebral palsied children Special schools are needed, admitting children with a combination of severe physical disability and normal intelligence This combination accounts for only 12% of all children with cerebral palsy, and it is unfortunate that these special schools have received so much publicity in recent years This publicity has obscured the great need to provide for the heavily handicapped child who, though trainable, is prevented by his poor intelligence from benefiting from any sort of education, and whose parents, if given some relief, can still manage to care for him at home This second type of special provision should be in a special occupation centre, equipped to care for, to train, and to treat backward children with severe physical disabilities

Although buildings have an important part to play in the management of children with cerebral palsy, it is not the buildings and the accommodation within them that matter, so much as the personalities of those who care for the children and who attempt to help their families Personalities are always more important than bricks and mortar, and personalities are particularly important in the management of children with cerebral palsy

Voluntary Agencies

Parents' Associations

Associations of parents of disabled children have three important functions

The first is to help its members to accept the inescapable fact of their children's disabilities Parents have a very important part to play in the management of their children, and they cannot be expected to play this part satisfactorily while they remain confused and frustrated Acceptance of the inescapable eases tension and enables the best use to be made of available resources

The second is to create a well-informed public opinion This in turn will ensure that official help will be forthcoming to meet the needs of all disabled children

The third is self-help in cooperation with local authorities Most local authorities are willing, but unable, to meet all the needs of the disabled Parents can help by providing additional facilities in schools and clinics

In the past ten years associations of parents of spastic children have sprung up throughout the country, until there are now in England and Wales over a hundred local parents' associations These associations have been quick to realise that publicity is a powerful weapon, and by means of their publicity they have achieved a nation-wide interest in cerebral-palsied children They have also been slow to realise that publicity, because it is so powerful, is also dangerous, particularly to themselves Many of the statements that have been published on behalf of the parents' associations have been inaccurate or over-optimistic There appears to be an urgent need to impress on some parents' associations some of the fundamental facts of cerebral palsy If the parents can be helped to accept these facts, they will be in a better position to help their fellow members and to create a well-informed public opinion

The parents' associations have used considerable initiative to raise large sums of money from a sympathetic public It is much easier to raise money for cerebral palsy than to spend it wisely, and much money may be wasted in providing facilities before the needs are accurately defined

Voluntary Societies

Although in recent years interest in cerebral palsy has spread widely, knowledge of the subject has lagged far behind, and many aspects remain unexplored Knowledge of its causes has advanced only a short way beyond the stage reached by Little (1862) nearly a century ago In the past fifteen years several attempts have been made to determine the size of the problems presented by cerebral palsy, and to plan what is needed for their management More recently several interesting methods of treatment have been used

The cause of cerebral palsy must be investigated in maternity hospitals and pathology laboratories Voluntary societies can assist these carefully planned long-term studies by means of research grants The management of patients with cerebral palsy must be investigated largely outside hospital and laboratories because it is concerned with the natural history of the condition and the effect which it may have on the child, his parents, and his family This type of investigation demands a flexible approach and is best conducted by clinical scientists, educationalists, and welfare workers, supported by a voluntary society with an interest in cerebral palsy It is probable that those who work in this way will be in the best position to collect information about the medical, educational and social problems which cerebral palsy presents, and to supply it to all who are interested in this branch of social service

Summary

As obstetric and pædiatric care has improved in this country, it seems likely that the incidence of cerebral palsy has increased Although prevention is important, management of the condition presents more pressing problems

The most important factor in the life of a young disabled child is the attitude of his parents to his disability Doctors, therapists, and teachers must help the parents to care for their children at home To overcome the social isolation which this entails, improved welfare services are needed

In this country there is still a shortage of accommodation in schools and institutions for backward children This is a particular hardship to the cerebral-palsy population which contains a large proportion of backward children More accommodation should also be provided in special schools and special occupation centres

In their concentration on the child and his disabilities, the parents' associations have tended to ignore the fact that the parents themselves often need as much help as their children

Much remains to be learned about the great variety of disabilities included in the term cerebral palsy The necessary inquiries can best be supported by voluntary societies having an interest in this branch of social service

I am indebted to Dr F J W Miller, reader in social pædiatrics in the department of child health, University of Durham, for much helpful criticism in the preparation of this paper

HEALTH SERVICE ESTIMATES

THE estimated gross total cost of the National Health Service[1] in England, Wales, and Scotland in 1958-59 is £677,679,845, compared with £649,322,885 in 1957-58 Appropriations-in-aid are estimated at £146,967,415, compared with £103,991,920 (an increase of £42,975,495), bringing the estimated net cost to £530,712,430, compared with £545,330,965 in 1957–58 (a decrease of £14,618,535) The cost of the hospital, specialist, and ancillary services is estimated at £434,758,709 in 1958–59, compared with £415,272,655 in 1957–58 (an increase of £19,486,135), under this heading advances to boards' revenue accounts are estimated at £398,595,000, compared with £382,660,150 (an increase of £15,934,850) General medical, dental, pharmaceutical, and supplementary ophthalmic services are estimated to cost £190,350,110 in 1958–59, compared with £184,496,980 in 1957–58 (an increase of £5,853,130) Grants to local health authorities are estimated at £30,797,800—an increase of £1,808,800 on the £28,989,000 in 1957–58

THE LISTER FESTIVAL

THE triennial Lister oration of the Royal College of Surgeons of England was given on March 28 by Sir Stewart Duke-Elder An account of it appears on page 781

In the evening, at the Lister festival dinner, Sir JAMES PATERSON ROSS, the president, said that the chief festivals of the college are named after John Hunter and Joseph Lister, “ the greatest of our forefathers ” Hunter by the experimental method had been the father of scientific surgery, but surgery remained dangerous and limited until Lister made it safe for the patient, and not until physiologists showed how the body reacts to operations was the patient made safe for surgeons Lister would be staggered by the increase in the scope of surgery since his time, and he would be bewildered by the intense activity of the college, which he knew as a quiet institution Setting, by its examinations, a scientific standard which benefits patients all over the world, the college had had to undertake postgraduate teaching because most medical schools are fully occupied with undergraduates It provided what amounts to an honours course in surgical specialties, and Lister would have approved its association with the University of London, whereby professors in the college are also teachers in the university Besides teaching, the college, through its research laboratories, had an eye to the future, and to the possibilities of preventive as well as curative surgery All this work could not be carried through unaided, and the President spoke gratefully of the many friends who believe in its cause—mentioning among others the benefactions of Sir Simon Marks and his associates, the Wellcome Trust, the Leverhulme Trust, the British Oxygen Company, Imperial Chemical Industries, Lord Nuffield, and Mr Edward Lumley The history of the college was such that it has no need to build for aggrandisement, but to be true to its heritage it must fulfil its trust

Sir James was responding to the toast of The College proposed by VISCOUNT CROOKSHANK The toast of The Lister Orator was given by Sir ARCHIBALD McINDOE, vice-president, who said that Sir Stewart Duke-Elder has earned and won more academic distinctions than any other man in British medicine, while the affection in which he is held would presently be shown by a celebration of his 60th birthday To the Institute of Ophthalmology, the love of his life, he had contributed a tremendous amount, and the institute in its turn had contributed a tremendous amount to the Commonwealth In his reply Sir STEWART said that he was proud to be chosen as orator, and glad also for the sake of ophthalmology—the subject in which Lister did his first piece of research

The guests were welcomed by Sir RUSSELL BROCK, vice-president, who had clearly left part of his heart in Australia, which must be visited if a surgical education was not to remain incomplete What the American in Nevil Shute's book said of Australian scenery—“ this is beautiful all right, by any standard in the world ”—was true, he felt, of every aspect of Australian national life

Sir CHARLES WHEELER, P R.A., comparing sculpture with surgery, said that sculptors are often asked “ What do you do if you cut away something you really want ? ”—to which the answer was “ we never do ” He wondered what surgeons did in such circumstances certainly the specimens of their work walking about the streets seemed to compare favourably with some modern pieces of sculpture Though many art schools now dispensed with anatomy, the Royal Academy, where William Hunter had been first professor of the subject, still believed in it they felt that holes cut in the human torso ought to be filled up Quoting Hamlet's passage, “ What a piece of work is a man the beauty of the world the paragon of animals,” Sir Charles added “ That is the material that you work on and we work on.” Knowledge was not enough there was need, too, of the mysterious something which art supplies In each profession there were those whose art transcends knowledge and makes for genius—having a sense of the whole drama of human existence One such was Lister

Public Health

FOOD-POISONING CAUSED BY CLOSTRIDIUM WELCHII IN COLD CHICKEN

MARTIN McNICOL
M B Glasg
FORMERLY SENIOR HOUSE OFFICER,
WESTERN INFIRMARY, GLASGOW

ELIZABETH J McKILLOP
B Sc Edin
ASSISTANT BACTERIOLOGIST, WESTERN INFIRMARY, GLASGOW

ALTHOUGH diarrhœa due to *Clostridium welchii* was first described over sixty years ago (Klein 1895) and attention has been drawn in recent years to food-poisoning caused by heat-resistant strains, this organism is not always sought even when an outbreak of diarrhœa in hospital is being investigated

The typical symptoms come on 8–20 hours after the infected food has been eaten (Hobbs et al 1953) and are highly suggestive though not pathognomonic If the necessary bacteriological examination is not undertaken, the outbreak is given some non-specific label such as “ hospital diarrhœa ”

One of us (E J McK) has investigated many cases of diarrhœa in hospital, and on five occasions in the past two years has noted a clear association between *Cl welchii* food-poisoning and cold chicken in the diet This hazard to patients in hospital is illustrated by the outbreak reported here

The Outbreak

Clinical Features

About 8 P M on Aug 6, 1957, 9 patients in a medical unit of thirty-nine beds developed a brief illness characterised by profuse diarrhœa and lower abdominal colic with disproportionately slight general upset. By the next morning all had recovered No specific therapy was given Diarrhœa was confined to the 15 taking light diet, among whom 9 were affected, the patients who ate special or ordinary diets were not affected The maid attached to the ward (case 16) also developed severe diarrhœa on the same evening The only item of food common to the patients and the maid was cold chicken, which was served at noon to those on light diet only The maid had eaten the chicken left over from the patients' lunch, and no samples of this food were therefore available for examination.

Bacteriological Investigations

On the morning of Aug 7, when the diarrhœa had almost completely settled, rectal swabs were taken from all 16 persons who had eaten the chicken

Each swab was plated directly on two horse-blood-agar plates and on MacConkey's medium Three tubes of Robertson's cooked-meat medium were then inoculated, followed by one tube of Robertson's cooked-meat medium with 10% sodium chloride and one tube of selenite-F medium One blood-agar plate was incubated anaerobically, all the other media were incubated aerobically One tube of Robertson's medium was boiled for fifteen minutes before incubation, and another for an hour, the third was not heated before incubation Previous experience has shown that positive results are obtained after fifteen minutes' boiling of the fæces in a few specimens when they are not obtained after the more usual hour's boiling

Next day the anaerobic blood-agar plates were examined for hæmolytic and non-hæmolytic *Cl welchii* Further strains were isolated by plating both the heated and the unheated tubes of Robertson's medium on to horse-blood-agar and incubating anaerobically The identity of all the cultures of *Cl welchii* was confirmed by showing that they produced α-toxin (lecithinase), and that this was specifically neutralised by *Cl welchii* α-antitoxin This test was done in tubes containing lecithovitellin prepared by the method of Macfarlane et al (1941)

Staphylococci were isolated from the Robertson's medium containing 10% sodium chloride by plating on to blood-agar and incubating aerobically Fluid cultures of suspected colonies were tested for the production of coagulase by a tube test with human citrated plasma All further references to *Staph aureus* or staphylococci in this paper denote coagulase-positive *Staph aureus*

The MacConkey's medium and the selenite-F medium were investigated in the usual way for intestinal pathogens None of the specimens contained salmonellas or shigellas

Non-hæmolytic heat-resistant *Cl welchii* was isolated from 11 and *Staph aureus*, in small numbers only, from 7 of the 16 rectal swabs examined (table I) Both hæmolytic and non-hæmolytic strains of *Cl welchii* were isolated from a large proportion of the cultures (12 of the 16) Of the 10 people with diarrhœa 8 had non-hæmolytic heat-resistant *Cl welchii* in their stools

Serological typing of all the non-hæmolytic strains of *Cl welchii* isolated, including the proved heat-resistant strains, was carried out by Dr Betty Hobbs of the Food Hygiene Laboratory of the Central Public Health Laboratory at Colindale Of the thirty-six strains examined, thirty were untypable by the available sera Untypable non-hæmolytic *Cl welchii* was isolated from 12 of the 16 persons at risk, and non-hæmolytic heat-resistant untypable *Cl welchii* from 9, of whom 8 had diarrhœa From 2 of the 3 who carried heat-resistant *Cl welchii* without having diarrhœa, the organisms isolated were of different serological types—type 5 and type 8 Possibly these two typable strains may have been unconnected with the diarrhœa

The staphylococci isolated from seven of the sixteen specimens proved to be of a wide variety of strains (table II) and were present in small numbers only, being isolated from enrichment but never from direct cultures

A month after the outbreak (Sept 13), when there was no diarrhœa, rectal swabs were taken from 16 patients in the unit, irrespective of the type of diet they were eating Only 1 patient who had been in the ward during the outbreak was sampled during this second investigation This sample was taken to provide a control observation The results of these cultures differ strikingly from those examined at the time of the outbreak A heat-resistant strain of *Cl welchii* was found in only 1 of the 16 patients examined, and *Staph aureus* in only 2

Discussion

The clinical picture was typical (Hobbs et al 1953) About eight hours after the ingestion of pre-cooked meat there was a brief illness characterised by colicky lower abdominal pain and diarrhœa The motions were watery and unformed but contained no mucus, blood, or pus There was no pyrexia, and systemic upset, as usual, was minimal

In the healthy adult this illness is merely an inconvenience, but in those already ill it may be prostrating, if not fatal When the illness is mild it is usually settling before note is taken of it, and complete investigation, including the food, is seldom possible Even in the present outbreak, in which food-poisoning was suspected early, samples of the suspected food could not be obtained This appears to be a not uncommon experience (Dickie and Smith 1957)

Non-hæmolytic heat-resistant *Cl welchii* was isolated from 11 of the 16 people exposed in this outbreak, and 9 of the 11 strains were untypable with Dr Betty Hobbs' sera The proportion of those with diarrhœa from whom an untypable strain was isolated (80%) corresponds to the previously reported figures for *Cl welchii* food poisoning (89% by Hobbs et al 1953) and is in keeping with the results reported for experimental *Cl welchii* food-poisoning (97% by Dische and Elek 1957) It seems quite probable that this outbreak was due to an untypable strain of heat-resistant *Cl welchii*

In the present outbreak the only item of diet taken by all the 10 persons with diarrhœa was cold chicken, and, though we have no direct bacteriological proof, it seems likely that this was responsible for the food-poisoning Cold chicken has already been noted as a potential source of *Cl welchii* food-poisoning (McClung 1945)

It has not yet been possible to establish with certainty how and when the chicken is contaminated with *Cl welchii*, and this problem is at present being investigated

We found no evidence in laboratory experiments that chicken is a more favourable medium than other meat dishes for the growth of *Cl welchii*, but the methods of cooling and storing boiled fowls often provide suitable conditions for the growth of such organisms

After cooking, the chicken may be left to cool in the broth, the two of which together provide an admirable medium for the growth of any *Cl welchii* that survives cooking or may subsequently gain access This is especially so in large kitchens such as hospital kitchens where many fowls may be cooked at one time and left to cool together with the broth in one container The mass of recently cooked chickens maintains a temperature favourable to bacterial growth for many hours particularly if the container is left at room temperature During transfer from the cooking-pot to the cooling container and during cooling they are liable to be exposed to hospital dust, which is heavily infected with *Cl welchii* The risk could be reduced either by cooking the chickens in a pressure cooker and keeping them sterile in this container until the time for serving them or by removing the birds from the broth after boiling and refrigerating them immediately and well separated from each other on shallow trays

Though contaminated, the chicken usually appears to be perfectly acceptable when served, and is regarded as palatable, on occasions it appears to be slimy, but it has never been foul-smelling or frankly putrid Thus it is served and eaten without hesitation, and the remnants are usually eaten or discarded before the onset of diarrhœa Patients who are receiving light diet are particularly liable to be affected, for cold chicken is an important part of their diet, these are the very patients liable to be most upset by such an episode

When diarrhœa was present, a wide variety of strains of *Staph aureus* was found in the stools of 7 of the 16 persons examined, in the control period they were found in *only* 2 This is a considerable difference, but one of us (E J McK unpublished work) investigating many cases of hospital diarrhœa has observed that the incidence of *Staph aureus* in fæces is higher in patients with diarrhœa, whatever the cause, than in patients without diarrhœa We think that this is the explanation for our findings in respect of *Staph aureus* and we do not hold the staphylococci responsible for the diarrhœa

In the present investigation the use of rectal swabs proved satisfactory, and in this type of outbreak the rectal swab has much to commend it All the persons at risk were examined with great convenience and complete certainty, whether they had diarrhœa or not Investigation did not depend on the chance that a sample of stool would become available at a convenient moment and that someone would remember to send it for laboratory examination An investigation of all at risk was thus possible It may be that, as indicated by Hobbs et al (1953), the negative results in the 2 patients with diarrhœa were due to the use of rectal swabs, but we think that the completeness of the sampling justifies the use of this method

Summary

A brief outbreak of "hospital diarrhœa" is described It was due to heat-resistant *Clostridium welchii* carried by cold chicken

Hospital patients whose diet contains cold chicken tend to be those given light diet

These are the very patients in whom even a brief attack of diarrhœa may be particularly troublesome

Our thanks are due to Dr T N Fraser for allowing us to report this investigation of patients under his care, and to Dr Betty Hobbs for the serological typing of all the numerous strains of heat-resistant *Cl welchii* from this outbreak

Scotland Increasing Mortality in Older Men

THE report of the Department of Health for Scotland[1] draws attention to the smudge on the generally satisfactory picture of that country's health while the death-rate is falling in all other groups, that in men in the second half of life is rising This increase cannot be attributed to the rising age of the population, and it means that some morbid process or processes must be on the increase At these ages "there are very few causes of death that do not affect males more than females", but the chief causes are the heavier liability of men to lung cancer and to cardiovascular disease, especially coronary thrombosis "Were it not for these two causes the male death-rate would be declining at approximately the same rate as the female although remaining at a higher level"

In Scotland the mortality from all causes in men aged 55-64 has risen over the past ten years, but in England and Wales the rate in this group has remained about the same, though the rate in men aged 65 and over has increased In England and Wales the rate remains much the same, though fluctuating, in women aged 75 and over, and has fallen in all other age-groups

The general improvement in younger people is exemplified by the infant-mortality rate, which in 1957 remained at the previous year's low record, the stillbirth and maternal-mortality rates, which were the lowest ever, and the tuberculosis death-rate (13 per 100,000, compared with 66 per 100,000 ten years previously) The number of notifications of tuberculosis rose from 5915 in 1956 to 7859 in 1957, because of the mass-radiography campaign, in which 1,319,867 people were radiographed

After cardiovascular disease and cancer, accidents caused most deaths in Scotland Bronchitis was the fifth commonest cause of death but caused most absence from work The influenza epidemic was a relatively benign one, but there were 90 deaths from it in one week—a figure rarely exceeded before Children's teeth continue to give cause for concern, at dental inspections of children aged 12, 20–30% of all teeth were recorded as missing, decayed, or filled

Outbreaks of Staphylococcal Infection

BECAUSE of staphylococcal skin infections in newborn babies, the maternity ward of the Southern General Hospital, Glasgow, is being closed There is no reason to believe that there is any connection with the outbreak in the Royal Maternity Hospital, Glasgow, three months ago, when 2 babies died[2] The ward is emptying gradually as patients become fit to be moved, no new patients will be admitted till the ward has been disinfected Castle Hill Maternity Hospital, Shaftesbury, Dorset, has also been closed and disinfected because of an outbreak of skin infection in babies[3]

Clean Air Act

THE Minister of Housing and Local Government has laid before Parliament regulations[4] setting out the exceptions to the ban on dark smoke[5] The exceptions are designed to allow for such essential operations as cleaning the fires of furnaces, which may necessarily involve emission of dark smoke for short periods Further regulations[6] add certain industries to those controlled by the Alkali Act rather than the Clean Air Act

River Pollution

THE Rivers (Prevention of Pollution) Act, 1951, required the consent of the Minister of Housing and Local Government before a river board might take proceedings under the Act for pollution caused by sewage or trade effluent This requirement was limited to seven years, but the report[7] of the trade effluents subcommittee recommends extension of the period by three years to 1961

Medicine and the Law

Diminished Responsibility

THE Court of Criminal Appeal gave its reasons for allowing the appeal of a labourer, aged 52, who was convicted of the capital murder of a 15-year-old boy The defences put forward were (1) that in killing the boy the accused was suffering from diminished responsibility as defined by section 2 of the Homicide Act, 1957, and was accordingly not guilty of murder but of manslaughter, (2) that the murder was not in the course or furtherance of theft (as alleged by the prosecution) so that even if the defence of diminished responsibility was not accepted the murder was not capital On March 24 the court allowed the appeal on the first ground and substituted a verdict of manslaughter[1]

The LORD CHIEF JUSTICE said that the second ground of appeal need not be considered and the court gave no decision on it The accused was a confirmed practising sodomite and there was evidence of some association between him and the boy, who was not seen alive after 4 30 P M on Nov 18, 1957, when he left a new job, having previously collected wages due to him from a former employer The boy's mother received three anonymous postcards, the first of which stated that the boy had gone to London as a woman was after him, the second that he was living in London with prostitutes, and the third that he was dead All three were written by the accused, who also wrote anonymously to the police to say that the boy's body was in the Tyne, and also accusing the boy of sodomy On the same day, he gave himself up to the police and described how he had killed the boy by smashing his head with a glass bottle filled with water and then with a claw hammer That was confirmed by postmortem examination The body was found cut in half and disembowelled and stowed in a sump under a boxing hall in Newcastle The accused, in a statement to the police, alleged that he had killed the boy because the boy was demanding money from him He also stated that he had killed the boy for his wages

On the issue of diminished responsibility none of the facts were disputed The defence called three medical witnesses Dr I G W Pickering, the senior medical officer of Durham Gaol, Dr R Orton, consultant psychiatrist at Newcastle General Hospital, and Dr T M Cuthbert, physician-superintendent of St Luke's Hospital, Middlesbrough, all three of whom had personally examined the accused The prosecution did not challenge the opinions they had formed All agreed that he was not insane within the McNaughten rules, but they were all satisfied that his mind was so abnormal as substantially to impair his mental responsibility, and gave their reasons for that opinion The evidence was clearly enough to shift the burden of proof thrown on the defence by section 2 of the Act of 1957, yet no medical evidence was given by the prosecution in rebuttal

What were the facts or circumstances which would justify a jury in coming to a conclusion contrary to the unchallenged evidence of those gentlemen? While emphasising that the decision in these cases, as in those in which insanity was pleaded, was for the jury and not for the doctors, the verdict must be founded on evidence If there were facts which would entitle a jury to reject or differ from the opinions of the medical men, the court would not, and indeed could not, disturb their verdict, but if the doctors' evidence was unchallenged and there was no other on that issue, a verdict contrary to their opinion would not be a true verdict in accordance with the evidence Here there was evidence of premeditation, but an abnormal mind was as capable of forming an intention and desire to kill as one that was normal, it was just what an abnormal mind might do The revolting nature of the crime itself would cause most people to say that it was the work of a maniac, and the court could well understand that a jury faced with such a crime committed by a sodomite would think that such a creature ought not to live, and that a verdict involving a capital sentence was the only one appropriate But Parliament had altered the law and decreed that if killing was committed by a person whose abnormal mind had seriously diminished his responsibility, the verdict was to be manslaughter and not murder The Criminal Appeal Act, 1907, directed the court to allow an appeal if they thought that the verdict of the jury should be set aside on the ground that it was unreasonable or could not be supported by the evidence Having regard to what they thought must have affected the minds of the jury the court would not care to say that the verdict was unreasonable, though they felt bound to say that it was not supported by the evidence The fact was that there was unchallenged evidence that the accused was within the provisions of section 2 of the Homicide Act and no evidence that he was not

Length of Pregnancy

A husband and wife resided in Kenya In December, 1954, they ceased to live together and the wife returned to England The husband spent a leave with her in England between April 22 and May 14, 1955, and sexual intercourse took place on the first or second night of that leave In the early morning of Dec 2, 1955, the wife gave birth to a 6 lb child at a nursing-home Subsequently the husband ceased to maintain the wife and she applied for an order against him on the ground of his wilful neglect to provide her with reasonable maintenance The husband alleged that he was not liable to pay maintenance since, inter alia, the wife had committed adultery with an unknown man in about February or March, 1955, as a result of which the child was born, he asked the court to infer that the child was not his as, after December, 1954, no intercourse had taken place between him and his wife save during the leave period, and the child was a normal full-time child without any signs of prematurity

Mr Justice COLLINGWOOD said that the matron of the nursing-home at which the child was delivered had said in evidence that she had no doubt that it was a full-time child The medical experts who had given evidence were in agreement as to the signs of prematurity but disagreed as to whether all or any of them would have been present

Dr C G Nairn, on behalf of the wife, had said that all or any of the recognised signs of prematurity would not be necessarily present in any one given case, and that none of them would invariably be present, that the textbook average of a 280-day period of gestation was reckoned from the onset of the last menstrual period but that the expected date of birth could not be worked out by reference to the date of sexual intercourse alone, and it was necessary to go back to the first day of the preceding menstrual period and add 280 days which would then give an approximate date of delivery at the best Dr Nairn's view was that to the 224 days (April 22/23 to Dec 2) 21 days could be added, that was a total of 245 days of fœtal life, and, where, as in the present case, there was evidence of irregularity in periods, he would add 26 days in the absence of definite evidence as to the presence of a menstrual period —which would bring the total up to 250 days He had said that assuming that there was a proper menstrual period and that 21 days only had to be added, a fœtus of 245 days duration would not necessarily be so premature as to be obvious, he would call it an eight-month child and from his experience it was impossible to distinguish an eight-month from a nine-month child with any certainty He agreed with *Taylor's*

---

[1] See *Lancet*, April 5, 1958, p 736

Medical Jurisprudence[1] and with the evidence given by Dr Roques in *Clark* v *Clark*[2] where it was held that a child born 174 days after the earliest date when intercourse could have taken place could be legitimate Dr G H Dodds, who had been called for the husband, had not agreed with the statement in *Taylor* nor with the evidence of Dr Roques, she would not admit the possibility that the child could have been the result of intercourse on April 23, 1955, and yet show no signs of prematurity She agreed that it was permissible to add 21 days, but not that one must do so

The question for His Lordship was whether the medical evidence had satisfied him beyond reasonable doubt that the wife had committed adultery The answer was that it had not He could not disregard the evidence of a witness of the experience and status of Dr Nairn and accepting this evidence, he was satisfied that the child born on Dec 2, 1955, could have been the result of intercourse on April 22/23, 1955

Parliament

Disabled Persons (Employment) Bill

ON March 31 Mr ROBERT CARR, parliamentary secretary to the Ministry of Labour and National Service, in moving the second reading of this Bill, said that its purpose was to implement the few recommendations of the Piercy Committee on the rehabilitation, training, and resettlement of the disabled[3] which required legislation It was a small Bill because the committee had come to the conclusion that the statutory framework of the services was basically satisfactory and had centred their recommendations on how the services could be more effectively used The main provisions of the Bill are as follows

The minimum age for attendance at vocational training courses and industrial rehabilitation courses is reduced from 16 to the school-leaving age Courses will thus be available for boys and girls immediately on leaving school, and the present gap will be avoided

The minimum period of disability before a person becomes eligible for registration is increased from 6 months to 1 year

The powers and duties of the local authorities for the employment and training of the disabled are transferred from the jurisdiction of the Health Ministers to the Minister of Labour The local authorities' responsibility for welfare and aftercare will remain under the jurisdiction of the Health Ministers as at present

In the debate Mr SOMERVILLE HASTINGS said that he was uneasy that these services should drop the pilotage of the Ministry of Health He appreciated that the change would be administratively convenient, but disability was largely a medical problem and he thought that it would be to the advantage of the disabled if there were always a watching brief on health available to them In their training, in the selection of occupations for them, and in the supervision of their progress, recovery, and capacity for new work, medical considerations must always come in He hoped that under the new arrangements this would not be forgotten

In his closing speech Mr CARR gave an assurance that the local-authority services would not be covered by the block grant, but would remain direct-grant aided

QUESTION TIME

Children in Mental Hospitals

Mr N N DODDS asked the Minister of Health what was being done to establish small units throughout the country for giving treatment to children who are acutely ill so as to eliminate the need for placing them in mental hospitals primarily devoted to adults, and sending them so far away as to deprive them of visits by relatives and friends—Mr DEREK WALKER-SMITH replied There are 17 special units for mentally ill children in England and Wales 10 of these are administered in association with a mental or neurosis hospital, all these are in buildings separate from those used for adult patients 9 other units are planned or under consideration Because the number of children who suffer from mental illness (as distinct from mental defect) is fortunately comparatively small, admission to a special unit may involve sending them farther from home than would admission to the mental hospital serving the area in which they live

Mr DODDS asked the Minister what consideration had been given to ending the detention of children at Rampton Mental Hospital—Mr WALKER-SMITH replied Alternative arrangements are not available for these children who are of dangerous or violent propensities They are transferred to other care as soon as this is warranted by improvement in their condition

Review of Mental-defective Patients

Mr DODDS asked the Minister what progress had been made in reviewing the cases of mental-defective patients with a view to ending compulsory powers, consequent upon the instructions issued on Jan 16—Mr WALKER-SMITH replied At March 25 hospitals had submitted 9122 recommendations and of these 5155 patients have been discharged from orders to remain in hospitals on an informal basis

Merit Awards

Mr KENNETH ROBINSON asked the Minister of Health the total numbers of consultant physicians, surgeons, and psychiatrists in England and Wales, and what was the number of merit awards in each of the three categories, showing A, B and C awards separately

Mr WALKER-SMITH replied On Dec 31, 1957, the figures were as follows

Specialty	Number of consultants	Awards			
		A	B	C	Total
General medicine	822	59	151	263	473
Mental health	614	6	20	63	89
General surgery	863	62	138	256	456

NOTE If a consultant practises in more than one specialty, he has been included in each.

Poliomyelitis Vaccine

Mr S S AWBERY asked the Minister if the supply of poliomyelitis vaccine and Salk vaccine was now sufficient to meet British requirements, what proportion of schoolchildren had so far been inoculated, and when he expected 100% to be inoculated—Mr WALKER-SMITH replied Purchases of poliomyelitis vaccine, including Salk, are being kept under constant review in the light of the number of registrations for vaccination Separate figures for schoolchildren are not available, but at the end of February 37% of all the children in Great Britain who had been registered had had two injections and a further 11% their first injection It is the Government's aim that vaccination should be available by the summer for those in the priority groups who have registered

Mr R S RUSSELL asked the Minister if he would arrange for local authorities which had more anti-poliomyelitis vaccine than they needed at the moment to transfer some to those which did not possess enough for their immediate needs—Mr WALKER-SMITH replied While no authority has more vaccine than is needed to vaccinate its registered children, I am aware that some authorities which at present have vaccine in hand are giving others temporary assistance by mutual arrangement, and I am encouraging this Of the total quantity of vaccine issued to date 62% has been of British manufacture

Cost of Antibiotics

Mr A M SKEFFINGTON asked the Minister why the one firm supplying specialised antibiotics was not subject to cost investigation —Mr WALKER-SMITH replied Some 15 firms supply specialised antibiotics to the National Health Service, and, of these, 2 firms are each the sole supplier of one particular drug For the supply of these two drugs to hospitals the Ministry of Health negotiates running contracts, which do not provide for cost investigation because the firms have so far been unwilling to accept a costing clause and I have no power to compel its inclusion

Birmingham	4 11 4	4 15 3	4 19 11	5 7 10	5 17 0	6 4 5
Manchester	4 12 0	4 17 1	5 0 9	5 10 5	6 1 6	6 9 2
Liverpool	5 12 5	5 18 6	6 4 4	6 14 11	7 6 3	7 16 6

In *some regions more than in others revenue expenditure is increased* by the provision of services, at teaching or non-teaching hospitals, for patients from other regions No estimate is, however, available of the effect of this upon the figures

National Health Insurance Contributions

Mr FRED BLACKBURN asked the Chancellor of the Exchequer by how much the weekly contributions for National Insurance and Health could be reduced if such contributions ceased to rank for tax relief —Mr D HEATHCOAT AMORY replied By about a shilling in the case of a male employee over 18, on the assumption that the extra revenue was devoted to the National Insurance Fund

Nursing at Mental Hospitals

The rate of recruitment of nursing staff to *mental* and *mental*-deficiency hospitals has improved in the last two years with an increase in the number of both men and women students The figures are as follows

—	1955	1957	Increase
(*a*) *Total nursing staff*			
Whole-time	26,713	28 443	+1730 (*6*%)
Part-time	9130	9953	+ 823 (*9*%)
(*b*) *Student nurses* (*included in* (*a*))			
Whole-time—Male	1708	2426	+ 718 (*42*%)
,, Female	2518	3277	+ 759 (*30*%)

In England Now

A Running Commentary by Peripatetic Correspondents

I SUPPOSE histories are a good thing I recall Sir Luke telling us when we were boys "Pay attention to the anamnesis, gentlemen, and the rest follows as the night the day" To him (and also to all neurologists I have since met) the physical signs could be made to support any diagnosis the history had suggested Perhaps it was this fact that decided me, in later life, not to pay too much attention to the patient's utterances, which are, after all, subjective, highly coloured, and possibly implanted by his wife, the neighbours, or his study of the Sunday newspapers To me the honest physical sign was everything, I spent long hours seeing if the patient knew which way I was moving his toes (holding only the lateral aspects, of course) I decided that a good laboratory test was worth an hour of talk and I always had an excuse for the lab if they baulked at doing the ketosteroids just *once* more The genetic mutations that must have resulted from my X rays now appal me

But as old age creeps on and the chromium plate is quite worn from the margins of my stethoscope, I must confess to a certain lethargy—a disinclination to budge from the comfort of the armchair "Tell me all about it," I say and fill my pipe I feel disgruntled when obliged to lay stethoscope on chest "No need to take all that lot off, old chap," I say, listening through his waistcoat Very reprehensible, I know, but I reckon I'll live longer, though I suppose there's a chance my patients won't Still, I do think I used to overdo the examining side of things in the old days It heartens me to see these studies of observer error makes me remember all sorts of times when different physicians heard different murmurs in the same patient after all if radiologists differ on shadows why shouldn't the stethoscope lead to dispute? When Sir Luke said "A diastolic murmur, boy, can't you hear it?"—he may have heard one, but that doesn't mean it was actually there

The final vindication of my new outlook came from a couple of cases I heard of recently The first was a young lady who had been through the mill at some fertility clinic to the extent of having air pushed around (with normal results) Some time afterwards a psychiatrist suggested that her sterility was probably due to the fact that she had not had sexual relations for some years The other one was a young man with exceptionally large masseters diagnosed as an atypical variant of pseudohypertrophic muscular dystrophy Long were the conferences and a muscle-biopsy was done but was normal Legend has it that the new H P asked the chap "What do you do when you're worried?" "I clench my teeth very tight, Doctor," he said Yes, I think Sir Luke was right all the time

* * *

The peripatetic discovery (March 29) of a single pedal, in a good state of preservation, lying on a public highway has excited the interest of bicycle historians everywhere As I see it, the circumstances point to the pedal having become detached from the machine at a moment when the rider's foot was not in contact with it Otherwise he could hardly have disregarded its loss

It therefore becomes of vital interest to know the gradient of the road at the site of the find For if the pedal was lying, as one must hope it was, half-way down a good long hill, its presence there could be regarded as presumptive evidence of the survival of at least one member of a species of cyclist which all the most recent authorities have presumed to be extinct in this country, though occasional specimens were still to be found earlier in the century—mainly, for some unexplained reason, among country clergy I refer, of course, to that type of rider who, scorning (or perhaps distrusting) the new-fangled "free-wheel", was forced while coasting downhill to disengage his feet from the pedals and rest them temporarily on brackets attached for the purpose to the front fork The loss of a pedal unbeknown to the rider at such a time is readily attributable to the exhilaration produced by the downward rush, while even if he were conscious of it, his failure to stop and retrieve the component so vital to his progress beyond the foot of the hill may be explained by the fact that a fixed wheel was, in this species, usually associated with rudimentary brakes, if not with their total absence

If, on the other hand, the find was made on a level stretch, one is forced back on a more prosaic explanation Tuberculosis of the knee-joint in early life had left the cyclist with one stiff leg, forcing him to rely for propulsion on the unaided efforts of the other When, therefore, the unused pedal fell off one day, its loss left him unmoved As a matter of fact the thing was always getting in the way of his lame leg and he had been meaning for months to take it off anyway, only he could never find that damned spanner

* * *

Rural sanitation is full of surprises, the conditions in and around shallow wells, for example I was inspecting drainage and water arrangements at a country house last week and noticed that the shallow well which was the sole supply of drinking-water had a well cover raised about 2 ft above ground level on top of a concrete wall, and that the ground for some distance around was adequately concreted, thus excluding surface contamination of the well The well cover was unusually high, but nevertheless I congratulated the house-owner on his initiative and hygienic standards, only to be told that the work had been done by the previous owner of the house, not in the interests of hygiene, but to provide himself with a mounting-block!

* * *

The Mandarin's sudden appearance for a consultation was an unusual event in our Thames Valley backwater His card bore a West-end address and "late of Peking" with, I presume, his name and "Sweet Flowering Twig" in brackets for the benefit of those ignorant of Pekinese, or more probably High Manchu His high-pitched voice told me he was seventy-eight and that his name was McConachie He could easily have been ninety

A glance at his face, like dried-out putty, his pin-point pupils, his emaciation, and I saw his whole case-history in a flash Unable to obtain heroin, cocaine, and the like in his own milieu, he was travelling afield in his remarkably fine Bentley (with an even more remarkable blonde) pleading intractable sciatica—a shot of pethidine plus script for two dozen ampoules would tide him over the weekend party at Henley I saw him in his red and gold bedragoned robes, long mustachios adroop, moist napkins pressed to his brow, the gold nail-shields removed to scoop more easily his winnings at Fan Tan (does anyone play Mah Jong?), twitching his ivory fan, whilst the bead curtains silently parted to disclose the youngest tea concubine I saw his short pigtail by which the spirits would whisk him to transports of celestial delight when mortal span had ceased, and, brooding over all, the inscrutable East—the Winter Palace, the Last Empress, Somerset Maugham, and Fatalism

But there he was, alive and kicking off his sandals Emanating a faint whiff of burning joss-stick, with hands clasped and hidden in his sleeves, he bowed low and slow from the waist, and—Confucius bless him—paid me half-a-guinea for my diagnosis, prescription, and prognosis of his athlete's foot

* * *

I rang the boy on the office phone The typist answered

"Is Jackson there?"

"I'll send him in" And before I could say more, she had put down the phone

A moment later Jackson appeared

"I didn't mean her to send you in," I started apologetically "I just wanted you on the phone" But Jackson had disappeared A moment later the phone rang

"Jackson here"

A bright young thing in whom a possible diagnosis of glandular fever had been raised—and the necessary investigations ordered—asked with a blush on the next ward round whether her Beau Brummell was positive

Letters to the Editor

PRE-ECLAMPTIC TOXÆMIA

SIR,—In his ingenious explanation of the ætiology of pregnancy toxæmia, Professor Platt (March 15) invokes an antigen-antibody reaction between fœtus and mother —"the condition being akin to rhesus incompatibility in reverse"

The kidney has been shown to be involved in antigen-antibody reactions

Pressman[1] has confirmed earlier findings that all available types of antisera are capable of nephrotoxic action After the injection of antistreptococcal serum impregnated with radioactive iodine, radioactivity was found only in the glomerulus, none being transported into the tubule This evidence of ischæmic spasm of the renal cortex is supported by Hartman's[2] demonstration that injection of an anti-cortex serum, which he attributes to spasm of the renal afferent arteries, reduces the number of glomeruli in the kidney—a happening that may explain the ultimate anuria consequent on renal homotransplants There is also much evidence that renal cortical ischæmic states can account for "toxæmic" manifestations[3]

I believe, however, that Professor Platt's hypothesis is untenable for several reasons It does not explain (1) why toxæmia is pre-eminently a disease of the primigravid, (2) how it can occur post partum, or (3) why it should sometimes recur at labour, days after subsiding on the death of the fœtus Furthermore there are two possible sources of error in the compilation of the statistics—first the insistence on the eventual presence of albuminuria for the diagnosis of toxæmia, and secondly an implied acceptance of the equal accuracy of diagnosis in the two generations—an equality disturbed by medical awareness of the condition and the greater facilities for antenatal supervision in the younger

By their findings, Professor Platt and his colleagues exclude the possibility that only one gene is responsible for pre-eclampsia, but they still think that several different genes may be capable of causing the disease There is recent proof, however, that this cannot be so

The failure of renal homotransplants to take seems to be based on a specific immunological reaction Such a reaction is absent in identical twins, for renal homotransplantation has been effected in three sets of identical twins (Merrill[4]) In the light of this, a case-report just published by Brown[5] needs scrutiny

It concerns a first pregnancy, with identical twins, which was entirely normal up to the 20th week From then until the 24th week the patient had acute hydramnios and "imminent" eclampsia Rational treatment by amniotomy overcame the excessive uterine stretch, and the signs of toxæmia subsided The hydramnios did not recur and the pregnancy continued for a further 16 weeks perfectly normally At birth one twin was in a papyraceous state its length of 15 cm indicated that it had perished much before the 24th week The structure of the placenta and the single sac showed that the twins were identical

If there had been any particular genes in the fœtus papyraceus responsible for the pre-eclampsia, the same genes, in the surviving twin, would have perpetuated the toxæmic process The disappearance of the toxæmia excludes a genetic intrusion into the ætiology

This case is, I believe, sufficient to refute Professor Platt's thesis—unless perhaps he argues that his hypothetical factor, which may protect the mother after her first toxæmic pregnancy, can develop on the intrauterine death of one twin

SIR,—My interest in the paper by Professor Platt and his colleagues prompts me to ask whether they would be kind enough to furnish the following further particulars

(1) How many of the women graduates or wives of graduates had had their blood-pressure taken before pregnancy?

(2) At what stage of pregnancy the hypertension, the hypertension+proteinuria (H+P) or the hypertension+œdema (H+O) developed?

(3) Whether the 8 women who had toxæmia in their second pregnancy had it in their first, and

(4) The perinatal mortality associated with the "pre-eclamptic toxæmia"?

It is indeed strange that at a time when well-conducted antenatal clinics are able virtually to abolish eclampsia the term pre-eclampsia should remain so fashionable Apart from causing maternal death or damage, or fœtal death or damage, "pre-eclampsia" possesses a merely academic interest Leaving hypotheses aside we have found at Bradford that the perinatal mortality associated with hypertension, whether essential or occurring during pregnancy (about 2500 cases) was between 5% and 6%, with H+O the same, with H+P, 20%, and with eclampsia approximately 50% Further, our figures show conclusively that the earlier the onset of H+P during pregnancy the more likely will be the mother to have either hypertension or H+O or H+P in subsequent pregnancies A woman who develops acute eclampsia during the 39th or 40th week of pregnancy will most likely remain normal throughout subsequent pregnancies, whereas a woman who develops H+P at or about the 34th week of pregnancy in two successive pregnancies, notwithstanding adequate antenatal care, is incapable of a normal pregnancy apart from denervation of her internal iliac vessels or some form of sympathectomy It is, therefore, essential to differentiate these types of cases and not lump them under the meaningless term of pre-eclampsia

I heartily agree with Professor Fekete (March 22) when he stresses dysharmonious function of the various hormones rather than the overactivity of one as the cause of "pre-eclampsia", and that hypertension and H+P occur not infrequently for the first time during the puerperium [1]

I have postulated that the "pregnancy toxæmias" are due to malnutrition and mechanical factors The malnutrition may be due to an inadequate or unbalanced maternal diet (but not to deficiency of vitamin B_1), or to an inadequate blood-supply to the placenta This latter inadequacy may be due to local or generalised arterial spasm or to hypoplasia of the arterial tree, and is for the most part associated with maternal defects which preceded the pregnancy So far as I can see this hypothesis alone explains the geographical distribution of eclampsia, the variation in its incidence caused by war, and the fact that whereas the incidence of hypertension during pregnancy is unaffected by antenatal care, that of H+P and toxæmic accidental hæmorrhage can be greatly reduced and eclampsia can be eliminated

Finally may I be allowed to make one observation on Professor Browne's delightful letter concerning postmaturity (March 1)? The importance of this problem cannot be gauged by studying hospital reports, for its significance may vary from country to country and from city to city Who would have believed it possible that the incidence of anencephalus in "Belfast and Dublin was approximately three times greater than in Birmingham, ten times greater than in Malmo and Lund, and fifty times greater than in Lyons"? [2] During 1947 we induced labour because of postmaturity in 334 patients and all the mothers and all the babies went home alive, the credit belonging to the registrars and nursing staff

Bradford G W THEOBALD

SIR,—Both Professor Browne (Jan 18) and Professor Fekete (March 22) appear to accept the view that there is hyperfunction of the adrenal cortex in normal pregnancy, although Professor Fekete does not believe that this organ plays a major part in the ætiology of pre-eclampsia While the raised levels of plasma-cortisol during gestation [3] and some of the clinical features suggest that in normal pregnancy the adrenal glands are hyperfunctional, recent evidence does not support this view

Migeon [4] and his colleagues, by demonstrating that the half-life in the plasma of administered radioactive cortisol is prolonged in normal pregnant women, have shown that the rise in plasma-cortisol may be due to delayed inactivation or utilisation In keeping with this hypothesis Appleby and Norymberski [5] have provided evidence that the excretion of 17-hydroxycorticosteroids in the urine of normal pregnant women does not increase greatly during gestation A study in this laboratory, as yet unpublished, of the excretion of the unconjugated cortisol and cortisone in the urine shows a similar moderate rise in pregnant women, although there was relatively no change in the conjugated steroids measured Moreover, little, if any, alteration in weight of the adrenal gland occurs during pregnancy in the human female, and the histological picture does not resemble that of prolonged stimulation by corticotrophin (A C T H) [6] Hyperfunction of the adrenal cortex is associated with excessive catabolism of the body proteins,[7] but in normal pregnancy with adequate nutrition considerable retention of nitrogen, potassium, and phosphate occurs and there is also evidence of an increase in the maternal cell mass [8-10] Thus isotopic, morphological, metabolic, and hormone-excretion studies provide no evidence to support the view that pregnancy is associated with hypersecretion of the important glucocorticoid, cortisol

Though it is possible that the inactivation or utilisation of aldosterone may alter in a way similar to cortisol there is as yet no evidence for this Our view that the increased amounts of aldosterone-conjugate present in the urine of pregnant women [11 12] is a reflection of a homeostatic response to an increased need for sodium conservation by the kidneys [13] is based on the assumption that the rate of aldosterone excretion in the urine is *indeed* related to its production by the adrenal cortex The low values obtained in pre-eclamptic toxæmia may be due to an inhibitory effect of the enlarged extracellular volume

POSTOPERATIVE HYPOTENSION

Sir,—It surprises me that in 1958 you can say, in your annotation of March 15, that occasionally the cause of postoperative hypotension "is less obvious, as when oligæmia from unobserved blood-loss during operation leads to" it Unobserved! "Unheeded" would often be apter Let the anæsthetist argue with the surgeon during the operation about blood-loss and the desirability of quantitative replacement He usually, for better or for worse, concludes his responsibility shortly after the patient returns to the ward Then what may the surgical resident find waiting for him there?

Perhaps not only the "unobserved" 1500 ml of de Wardener et al ,[1] but, far more often unheeded, the prospect of a postoperative ooze of another litre or so occurring during the next 24 or 48 hours

Donating blood, I may lose 540 ml without turning a hair or constricting a skin vessel But then I haven't had an anæsthetic nor have I a wound to heal nor an infection to prevent And not a drop more will leave the circulation This often-quoted analogy is an irrelevant one

Letheringsett,
Norfolk. J N Cozens-Hardy

SMOKING AND RESTLESS YOUNG MEN

Sir,—The far-fetched hypothesis that tobacco-smoking and lung cancer have partly a common cause in a constitutional factor is, as your annotation of March 29 points out, very difficult to accept Even if it was acceptable it would hardly affect the case against tobacco, but it and similar theories will continue to fog the issue so long as tobacco has defenders or until the cancer-smoking causal relationship is completely elucidated, or its existence proved beyond all possible argument by controlled experiment

In your same issue (p 657) Dr Doll and his colleagues report a controlled experiment proving that smoking, continued during treatment, delays the healing of peptic ulcers Surely experiments such as this should also be made to discover more completely many of the other relationships of smoking to health? In many cases the facts are in doubt, and as far as cancer is concerned the last refuge of the obscurantist and wishful thinker would be destroyed The national resources available for anti-tobacco education are necessarily limited, and there is therefore a sound ethical case for constituting some of the first beneficiaries of it into an experimental group This has been done with poliomyelitis vaccine and fluoridated water-supplies, in the latter case more to demonstrate the facts than to discover them Schools and places of employment, as well as residential areas, might determine the grouping, and a scientific study of motivation and of different techniques of education and persuasion might also be included in the experiment

London, S W 10 R B D Stocker

MORTALITY OF SEVERE HEAD INJURIES

Sir,—After reading the excellent article by Mr Maciver and his colleagues (Feb 22), I wish to draw attention to the dramatic response in patients with head injury to thiopentone cautiously given intravenously in dilute solution, after the initial shock has been combated[1] The patients improved greatly, in that hyperpyrexia and high blood-pressure were lowered and bronchial secretion and restlessness reduced

We feel that thiopentone has some coordinating action on the reticular activating system[2] and that the "lytic cocktail" is in some ways dangerous, by increasing the effects of anoxæmia in the tissues, particularly the brain

Amsterdam. T Wilhelmus

SEPARATION OF MOTHER AND CHILD

Sir,—I have long supported the "separation anxiety" thesis, even before it was as fashionable as it has become today It figured very largely in the psychopathology developed and taught by Hadfield,[3] Suttie,[4] and others at the pre-war Tavistock Clinic Their views were amply confirmed in the child-guidance clinic, and one had no need to devise any special theory, or elaborate statistical evidence, to appreciate to its full extent the protective role of the mother in creating the requisite emotional security for the young child's upbringing It was a natural corollary to pay attention therefore to anything disturbing the mother-child relationship, whether from within or from without

Separation of a child from its mother-figure undoubtedly *can* be traumatic, and an estrangement even more so But this is a far cry from Dr Bowlby's thesis (March 1) which has laid so much at the door of the *physical* separation of mother and child Dr Howells (March 29) rightly maintains that "Separation and privation are not synonymous terms", separation can and does occur without privation, as well as vice versa

Statistical investigations on the subject are valuable in their way, but, to repeat a platitude, one must ask for caution in their interpretation I still think that our prime need is for more and careful clinical studies of the *total* situation where mother and child have to be separated With regard to hospital separations it is many years now since I asked[5] for further inquiry into what kind of children are adversely affected? how far? and in what way?—including of course a study of the reverse process of recovery in those overcoming the "trauma" of separation

Exaggeration has provoked the inevitable reaction, and I was amused to read of Margaret Mead's outburst[6] calling the thesis "a new and subtle form of antifeminism in which men —under the guise of exalting the importance of maternity—are tying women more tightly to their children than has been thought necessary since the invention of bottle feeding and baby carriages"

One hazard which it seems we have not escaped is the premature dissemination to the public at large of opinions which as yet are not fully authenticated A recent pamphlet put out by the National Association for Mental Health[7] presents the problem moderately enough, but is sufficiently loaded to cause undue anxiety to already anxious mothers This April sees the centenary of the birth of Truby King, who in his turn tried to impose a rigid pattern of infant-feeding on the mothers of his day, which is now generally regarded as outmoded

[7] Bowlby, J Can I Leave my Baby ? 1958

Perhaps the crux of the matter lies in the discovery of the "great heterogeneity of personality organisation" which defies classification and asks for a patient and sympathetic understanding of each situation in its own right Finally I would call attention to the serious danger of using pathological reactions as a basis on which to erect standards of behaviour for normal people, in so doing are we not putting a premium on the element of adventure in really healthy living?

Bradford H EDELSTON

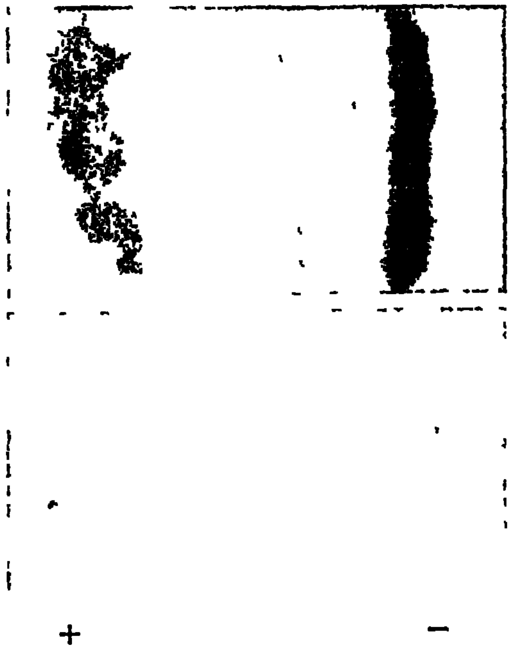
UNUSUAL URINE PROTEIN IN MYELOMATOSIS

SIR,—The new technique of electron microscopy has helped towards the understanding of the physical principle of glomerular ultrafiltration Glomerular capillary walls of kidney are structurally specialised, with channels and spaces somewhat similar to those of collodion membranes prepared for use as an ultrafilter [1]

In our experiments, by ultrafiltration of normal and pathological sera through collodion membranes of suitable porosity, ultrafiltrates were obtained, the patterns of which corresponded to the patterns of pathological urine proteins [2,3] The concentrated ultrafiltrates of sera were investigated by paper electrophoresis

We also examined serum ultrafiltrates from patients with myelomatosis and macroglobulinæmia In each case, electrophoresis revealed an additional electrophoretically homogeneous serum-protein fraction Even here we were able to find a similarity between natural and artificial ultrafiltrates

In one patient with myelomatosis we saw an interesting phenomenon [4] The simple paraproteinæmic serum fraction split, after filtration through membrane of a known porosity, into two clearly separated components, during analysis of ultrafiltrate proteins by paper electrophoresis (see figure) The splitting of this fraction we took to be a result of a change in the electrical charge on colloidal molecules caused by mutual action of membrane pores and protein particles during the filtration process



Above: Electrophoretic protein pattern of serum from a patient with myelomatosis shows a single γ-globulin fraction; below: Electrophoretic pattern of concentrated ultrafiltrate of the same serum shows two γ-globulin components Both electrophoretograms were done under the same conditions

As the discussion in your correspondence columns shows,[5–7] a similar phenomenon was sometimes seen in the sieving effect of the biological glomerular membrane on the blood-proteins passing into the urine In this connection the idea of an analogy between the glomerular membrane and the artificial collodion membrane may be useful

INSTITUTIONAL CARE OF THE MENTALLY ILL

SIR,—In the article by Dr Garratt and his colleagues (March 29) there is one point which I do not think should go unchallenged Under the heading of "supervision" they say that there "could be no reasonable objection" to the employment of general-trained nurses to attend to some of the less disturbed psychiatric patients

When this survey was being made, the psychiatrists were asked to designate patients who needed no (or minimal) psychiatric nursing supervision But this does not mean that general-trained nurses would be acceptable

What such patients require emotionally is the kind of competent mothering which is a fairly common skill in married women of mature age (our untrained part-time nurses tend to have it in good measure) Unfortunately, the pattern of general nursing training, with its emphasis on purely technical abilities, is still such as to spoil rather than to foster this kind of skill in human relationships Nurses in general hospitals tend to be far more upset by the presence of a "psychiatric patient" than is the community at large

I would therefore recommend that the psychiatric patient with minimal disability should be cared for either by untrained nurses (under psychiatric supervision), or, if the general-trained nurse is the only possibility, she should have been away from general nursing for long enough to have recovered from it—say, at least five years

Hollymoor Hospital,
Northfield, Birmingham J R MATHERS

PSYCHOSIS AND TREMOR DUE TO MECAMYLAMINE

SIR,—We have a gentleman in the ward at the moment with what we believe to be the mecamylamine toxic syndrome described by Dr Harington and Dr Kincaid-Smith (March 8)

He came to us seven months ago as an emergency with an episode of hypertensive encephalopathy, and while in the ward had a minor subarachnoid hæmorrhage His blood-pressure was 260 + /110 mm Hg and blood-urea 27 mg per 100 ml His recovery from these complications was uneventful but we found it necessary to keep him on a dose of 30 mg of mecamylamine six-hourly and he was later discharged on this dosage At this time his blood-pressure was 180/120 and his blood-urea 25 mg per 100 ml

He was followed up at regular intervals and made good progress In February he was normotensive and had a blood-urea of 45 mg per 100 ml

Two weeks ago he was readmitted because of a generalised coarse tremor and difficulty with his speech There was also some pruritus of the legs The tremor affected his whole body and was present at rest so that his bed shook It was accentuated by voluntary movement and so much so that he was unable to

---

5 Cummings, A J *Lancet*, 1957, ii, 598
6 Gobert-Jones, J A *ibid* p 1068
7 Owen, J A *ibid* p 1286

drink a cup of tea There were no hallucinations or other mental changes, however, and no localising signs in the central nervous system His blood-pressure was now 240/130 and blood-urea 66 mg per 100 ml

The mecamylamine has been withdrawn since then and there has been a marked improvement in his symptoms His tremor is such that he can now write legibly and speech is no longer slurred and jerky His blood-pressure remains at 240/140 and his blood-urea is 53 mg per 100 ml

This case seems to fit in with the syndrome described by Dr Harington and Dr Kincaid-Smith Three features we feel are of special interest (1) the very high dosage of mecamylamine, (2) the satisfactory response to withdrawal of the drug, and (3) the fact that only two blood-urea estimations during the whole illness have been slightly above the upper limit of normal In view of these facts we are not convinced that any part of his symptom complex was due to uræmia

JOHN A LENNOX

THE FUTURE OF THE PUBLIC HEALTH LABORATORY SERVICE

SIR,—Your comment (April 5, p 730) that the separation of the Public Health Laboratory Service from the hospital laboratory service is in places too wide deserves study

The field of the P H L S is bacteriology applied to preventive medicine, but between this and other branches of medical bacteriology it is no longer easy to draw a sharp line Is the throat swab taken from the child suspected of having scarlet fever to confirm the diagnosis or for the benefit of his contacts or of the community? The virtual disappearance of such diseases as typhoid fever, the radical changes in the management of tuberculosis, and the improved prognosis in, for example, puerperal infections, have all helped to confuse a distinction which was much clearer twenty years ago The isolation hospital and the tuberculosis clinic, both former preserves of the P H L S, are now administered by the regional hospital board Almost everywhere the general practitioner can send his specimens to the hospital laboratory Except for water and foodstuffs the number of bacteriological specimens provided by the health departments of local authorities seems to be less than it was The P H L S has done excellent work in diagnostic virology in many places, but it is only a matter of time before the hospital laboratories take advantage of the experience obtained in this field

The P.H.L S has had advantages in its generous scales of technical staff and equipment It has provided good opportunities for work with the minimum of interference and red tape It has developed an admirable ésprit-de-corps It has almost certainly done much to raise the standards of medical bacteriology in this country It has produced much original work of high quality and in particular has demonstrated the value of large-scale cooperative investigations Nevertheless it is now open to argument whether we can afford to maintain a duplicated bacteriological service except in those towns large enough to provide sufficient public-health bacteriology to keep one laboratory busy In the smaller towns public-health bacteriology seldom provides more than a part of the work of the P H L S laboratories which fill in their time with the leavings of the hospital laboratories and even compete with them for the custom of the general practitioners

It is not a question of abolishing the P H L S but of examining its structure and working to see how best it may take its share of the medical bacteriology without lowering its standards or forgetting its traditions The time is past when laboratories could be established and conducted on an empirical basis The planning of hospital services has advanced to the point where we can make a reasonable guess about the needs of the next twenty-five years The P H L S laboratories should be fitted into these plans as soon as possible, not by local and informal agreement but in accordance with some integrated design

A PROVINCIAL PATHOLOGIST

BUDGERIGARS AND POLIOMYELITIS

SIR,—Haunted by the budgerigar carrying polio virus, we have examined those sera of household pets still in our deepfreeze (dating from 1951 till March, 1958) for neutralising antibodies against all 3 types of poliovirus The sera were tested with a modified colour test in plastic plates in a dilution of 1 in 10 37 budgerigars, 4 parrots, 2 canaries, 52 pigeons, 2 cats, and 5 dogs had no neutralising antibodies in their serum, but 1 dog had antibodies against polio type-I in his serum

It seems that polio infection in household pets, at least in Holland, might be a rare event

F DEKKING

THE BURNING-FEET SYNDROME

SIR,—You have commented (March 8) on Bibile et al 's report[1] that they had failed to observe any significant difference in the proportion of cures obtained in the burning-feet syndrome between pantothenol (alcohol derivative of pantothenic acid) and a placebo Of 38 patients they treated with pantothenol orally or parenterally, 22 were either cured or improved On the other hand, out of 18 patients treated with a placebo, 11 were either cured or improved Dr Bibile and his coworkers have rightly concluded that pantothenic-acid deficiency was not the cause of burning feet *in the patients investigated by them*

On the other hand, the fact that pantothenic-acid deficiency may produce burning feet is suggested by a number of observations

In burning feet associated with signs of vitamin-B-complex deficiency, benefit has followed on administration of pantothenic acid[2] Defective acetylation of para-aminobenzoic acid, indicating pantothenic-acid deficiency, has also been reported in these cases[3] The work of Bean et al[4] has provided further evidence of the role of pantothenic-acid deficiency in burning feet By administering a pantothenic-acid antagonist to human volunteers, these workers were able to produce paræsthesia of the limbs, burning feet, and hyperactive reflexes When pantothenic acid was given, the paræsthesiæ, including burning feet, disappeared completely

In the light of this evidence, the question arises whether the burning feet investigated by Bibile et al were in fact of nutritional origin In this connection their observation that they obtained improvement in 11 out of 18 cases treated with a placebo alone would seem significant. Your annotation does not draw attention to this important point

The duration of the disease before treatment in their cases was reported to vary from as long as eighteen to forty-four

The virtual disappearance of such diseases as typhoid fever, the radical changes in the management of tuberculosis, and the improved prognosis in, for example, puerperal infections, have all helped to confuse a distinction which was much clearer twenty years ago The isolation hospital and the tuberculosis clinic, both former preserves of the P H L S, are now administered by the regional hospital board Almost everywhere the general practitioner can send his specimens to the hospital laboratory Except for water and foodstuffs the number of bacteriological specimens provided by the health departments of local authorities seems to be less than it was The P H L S has done excellent work in diagnostic virology in many places, but it is only a matter of time before the hospital laboratories take advantage of the experience obtained in this field

The P.H.L S has had advantages in its generous scales of technical staff and equipment. It has provided good opportunities for work with the minimum of interference and red tape It has developed an admirable esprit-de-corps It has almost certainly done much to raise the standards of medical bacteriology in this country It has produced much original work of high quality and in particular has demonstrated the value of large-scale cooperative investigations Nevertheless it is now open to argument whether we can afford to maintain a duplicated bacteriological service except in those towns large enough to provide sufficient public-health bacteriology to keep one laboratory busy In the smaller towns public-health bacteriology seldom provides more than a part of the work of the P.H.L S laboratories which fill in their time with the leavings of the hospital laboratories and even compete with them for the custom of the general practitioners

It is not a question of abolishing the P H L S but of examining its structure and working to see how best it may take its share of the medical bacteriology without lowering its standards or forgetting its traditions The time is past when laboratories could be established and conducted on an empirical basis The planning of hospital services has advanced to the point where we can make a reasonable guess about the needs of the next twenty-five years The P.H L S laboratories should be fitted into these plans as soon as possible, not by local and informal agreement but in accordance with some integrated design

A PROVINCIAL PATHOLOGIST

BUDGERIGARS AND POLIOMYELITIS

SIR,—Haunted by the budgerigar carrying polio virus, we have examined those sera of household pets still in our deepfreeze (dating from 1951 till March, 1958) for neutralising antibodies against all 3 types of poliovirus The sera were tested with a modified colour test in plastic plates in a dilution of 1 in 10 37 budgerigars, 4 parrots, 2 canaries, 52 pigeons, 2 cats, and 5 dogs had no neutralising antibodies in their serum, but 1 dog had antibodies against polio type-I in his serum

It seems that polio infection in household pets, at least in Holland, might be a rare event

F DEKKING

THE BURNING-FEET SYNDROME

SIR,—You have commented (March 8) on Bibile et al's report[1] that they had failed to observe any significant difference in the proportion of cures obtained in the burning-feet syndrome between pantothenol (alcohol derivative of pantothenic acid) and a placebo Of 38 patients they treated with pantothenol orally or parenterally, 22 were either cured or improved On the other hand, out of 18 patients treated with a placebo, 11 were either cured or improved Dr Bibile and his coworkers have rightly concluded that pantothenic-acid deficiency was not the cause of burning feet *in the patients investigated by them*

On the other hand, the fact that pantothenic-acid deficiency may produce burning feet is suggested by a number of observations

In burning feet associated with signs of vitamin-B-complex deficiency, benefit has followed on administration of pantothenic acid[2] Defective acetylation of para-aminobenzoic acid, indicating pantothenic-acid deficiency, has also been reported in these cases[3] The work of Bean et al[4] has provided further evidence of the role of pantothenic-acid deficiency in burning feet By administering a pantothenic-acid antagonist to human volunteers, these workers were able to produce paræsthesia of the limbs, burning feet, and hyperactive reflexes When pantothenic acid was given, the paræsthesiæ, including burning feet, disappeared completely

In the light of this evidence, the question arises whether the burning feet investigated by Bibile et al were in fact of nutritional origin In this connection their observation that they obtained improvement in 11 out of 18 cases treated with a placebo alone would seem significant. Your annotation does not draw attention to this important point.

The duration of the disease before treatment in their cases was reported to vary from as long as eighteen to forty-four months The fact that they obtained such gratifying results with placebo alone (cure or improvement in 11 out of 18 cases) seems to throw doubt on their nutritional origin It seems very unlikely that a syndrome of chronic malnutrition of several months' duration could be so successfully treated with a placebo in four weeks In the selection of their cases Bibile et al were apparently guided solely by the presence of paræsthesia of the limbs Their table listing the clinical features does not mention such signs of vitamin-B-complex deficiency as angular stomatitis, glossitis, scrotal dermatitis, &c On the other hand, all the cases of burning-feet syndrome that benefited from pantothenic-acid [3] had shown advanced signs of vitamin-B-complex deficiency In these cases hyperhidrosis was much more evident and actual aching in the limbs much less prominent than in the series of Bibile et al Evidently the two series were different not only ætiologically but also clinically

[4] Bean, W B, Hodges, R. E., Daum, K. *J clin Invest* 1955, 34 1073

Paræsthesia of the feet may of course have many causes, and it is obviously unjustifiable to attribute all burning feet to malnutrition In our own clinic in Coonoor, we see some burning feet unassociated with clinical evidence of malnutrition, in which naturally no nutritional therapy, including pantothenic acid, yields significant benefit Moreover, acetylation of *p*-aminobenzoic acid has been found normal in these cases It is possible that some of them are of functional origin, and may improve with suggestion and administration of placebo

TOTAL EXCHANGEABLE SODIUM IN HÆMORRHAGIC SHOCK

SIR,—Plasma volume is diminished in most cases of hæmorrhagic and traumatic shock There are, however, few data on the behaviour of the extracellular space in shock [1] We have investigated the question by continuous determination of ^{24}Na space (indicating total exchangeable sodium) in dogs in the normal state, in posthæmorrhagic hypotension, and after reinfusion of the blood

The dogs were given about 20 μc of ^{24}Na intravenously, and the ^{24}Na space was calculated after 3 hours by the usual technique Bleeding and reinfusion were carried out by the standard technique of Wiggers [2] (90 min at 50–60 mm Hg, 45 min at 30–40 mm Hg) The ^{24}Na space was repeatedly determined in the hypotensive period and after reinfusion for about 6 hours

Six dogs died in shock within 2–6 hours of reinfusion Six survived the 6-hour period In all the dogs which succumbed to shock the ^{24}Na space showed a progressive increase up to 25% of the control values In the survivors, there was no change in sodium space The plasma-sodium level remained unchanged in all experiments

As we have previously observed in nephrectomised dogs that the inulin space does not change in hæmorrhagic shock, the increase of the ^{24}Na space—with the plasma-sodium levels unchanged—can hardly be due to the increase of extracellular sodium Accepting inulin space as a measure of extracellular space, the increase in exchangeable sodium must be the consequence of the increment of intracellular sodium That part of the intracellular sodium which is not exchangeable under normal conditions probably becomes exchangeable in shock

A detailed account of our data will be published elsewhere

THE DOCTOR'S ATTITUDE TO HIS PATIENT

SIR,—Like Dr Ryle (March 1) I have been waiting for a gun of some calibre to sink Dr Clyne (Feb 1) and am only tempted to interfere by the absence of any such "official" armament and from the presence now of a second sail, Dr Pasmore (March 8)

I read Dr Clyne once and thought it was queer that the article had arrived there at all, then I read it again with more sympathy for his difficulties, and I have read it a third time but still cannot let him off I kept thinking he should look at Luke Fildes' picture, he would find there another doctor who could not say what was wrong with his small patient but at least was observing the clinical course Admittedly his vigil is hypocritical in being valueless to the child, but he may have learnt something himself I am sure that is not what Fildes wanted to express, he was after the love and devotion, but more factually that doctor's only hope was to know better next time I am using this example to suggest that Dr Clyne has been unfortunate in trying to hang his analytic weeds on an unsuitable peg, because they fall to a heap as certainly as it is obvious that when he received that call that morning he could not write his paper at the same time as know what was the matter with the child

Seen this way it becomes plain that his guilt-hostility discussion could never have arisen if his clinical wit and decision had not been clouded by his eagerness to pay attention to other things than the child's disease, you remember that Fildes kept the parents dark in the background, and Dr Clynes tacitly demonstrates the only person who took an objective view of the case, the patient's father, who is dubbed for his strength a weak character The document is therefore anti-clinical, Dr Ryle thinks it anti-scientific as well, but that does not concern me so much Anti-clinical it is, and the range is the same for the second sail, Dr Pasmore

You have offered him broadside by publishing his fuller article in the same issue (March 8) as his letter His basal error is the same as that of Colin Wilson, who wrote a most attractive book about a bunch of most attractive lunatics Unfortunately he tried to draw a social lesson from them and foundered on the fallacy There are lessons to draw from such people, either their lunacy with or without the charm, or the charm without the lunacy, none of these three is a social lesson, meaning a moral or ethic applicable to other people *Modern medicine is in the* same quandary towards the recently unearthed mass of minor neurotics, who always were present of course but did not go to doctors There is no social lesson to learn from these people and it is a fallacy to think there is, and if the profession swallows them whole it can only become neurotic itself, if it is wise it will take what it wants off this world (after all, who wishes to be unemotional?), and it will leave the rest either to recover, as many do, remain neurotic, as many do, or become psychoneurotic, as very few do It is however anti-clinical to move the couch too near the confessional and it brings queer reasoning Dr Pasmore betrays great pride and complacency when he unearths the fact that his "intelligent secretary" was not so much worried by the poliomyelitis of her cousin as the loss of her fiancé But what would have been the doctor's illumination if these trophies had been dug up in the other order, as they could have been?

This sort of inquiry is specious but not specific, all it says is that this patient is the sort of patient who is likely to make a muddle of a romance, fair enough, is likely to be greatly upset when it crumbles, fair enough, can also be upset by the poliomyelitis of her cousin, fair enough, is emotionally insecure, fair enough, but is quite capable of either a happy marriage or a useful life, or both, fair enough The emotional history should not have any direct influence on the doctor's clinical opinion, in this case, the reason why her legs were weak This reason may be functional as we all know, but the clinician reaches that opinion without the emotional history, and can give just as good advice and can get just as good a result without ever hearing it

SCANNER

SIR,—I thought Dr Ryle's letters were very refreshing, and Dr Pasmore's perhaps a shade irascible from one adept at suppressing parts of his personality I also confess to "outmoded obscurantism" and delude myself into thinking that I can "achieve a reasonable understanding without undergoing personality change" Nor do I see anything unsound in our giving what active, positive advice we truthfully think is most helpful, according to our own principles, biases, morals, religions, and backgrounds We are, doctors and patients, all irrational human beings in it together and, unfortunately, analysis or personality change, whilst making a doctor more aware of his own emotional characteristics (why "disabilities"?), may not make him wiser or kinder, warmer-natured or more intelligent, or less of a crank than he might otherwise have been

The negative, passive attitude (What do you think I should do doctor? Well, what do *you* think?) mistakenly assumes most patients to be unable, inwardly or outwardly, to criticise us, or our advice, to amend or to reject it, or indeed to have any sensible view of our fallibilities at all Conversely, to assume that analysis or personality change produces in the doctor a mind so aloof from its own peculiarities that it can be used on fellow humans as a "scientific instrument" betrays a humourless superiority of attitude, a conviction of post-analytical rightness, that some of us find the least acceptable facet of the psychiatric approach

London, S W 7 **BENJAMIN LEE**

SIR,—Dr Pasmore (March 29) has restated his case with vehemence but no new evidence

Can he cite references for his bald claim that "scientific inquiry has shown that the psychoanalyst cannot practise his specialty without undergoing an analysis himself, and recent research suggests that the general practitioner cannot attempt similar work in a limited field without undergoing some modified analysis or personality change"? Dr Pasmore may be convinced that psychoanalytical theory is true but he has no right to close his eyes to the fact that non-analysed psychiatrists and G P s who have never been to a Tavistock seminar are treating neuroses

One of the reasons for my original letter criticising Dr Clyne's article was to question its apparent assumption that the tenets of psychoanalysis were proven A widely held opinion does not constitute a scientific fact, and psychoanalysis remains scientifically dubious because it is full of untestable hypotheses and hence prone to repeated revision, schism, and inconsistencies, because it pays so little heed to allied sciences and because its claim to exclusive therapeutic efficacy remains unproved [1,2] Workers holding non-analytical views have reported results as good or better and usually quicker—e g, Phillips [3] and Wolpe [4]—and are able to explain and accept the effects of analysis, a tolerance not often reciprocated T A Ross, whose books [5,6] did so much to introduce psychotherapy into general practice, was much concerned lest the analysts, with their claim to exclusive truth, should gain control of the teaching of the neuroses, his warning [7] deserves re-reading today

London, N W 5 **ANTHONY RYLE**

MITRAL VALVOTOMY AND PREGNANCY

SIR,—That mitral valvotomy is valuable is established If, however, valvotomy is to be allotted its proper place in the management of the pregnant woman with mitral stenosis, it should be compared only with the best method of treatment hitherto available—namely, strict medical supervision allied to conservative obstetrics [8,9] Since therapeutic abortion is not only valueless but positively dangerous, it is unfortunate that Dr Wade and his colleagues (March 15) should join Das and Chesterman [10] in confusing this important issue by recommending valvotomy as a substitute for termination

In our recent series of 289 cases of rheumatic heart-disease complicated by pregnancy,[9] in which no therapeutic abortion was performed, 1 mother failed to survive the puerperium and 8% of all conceptions failed to survive the neonatal period Our conclusion that therapeutic abortion is of no value has been confirmed by Gorenberg [11,12] On the other hand, Jones [13] showed that abortion is dangerous he recorded 2 maternal deaths due to therapeutic abortion in a series of 352 heart cases In this series the fœtal wastage directly due to termination was 6 4% Fitzgerald et al [14] corroborate this in reporting 3 maternal deaths in 450 cases All 3 deaths followed termination

Valvotomy was performed during pregnancy in 3 of our 289 cases In each case mother and baby survived Dr Wade and his colleagues performed the operation on 12 pregnant women, but do not state the total number of cases from which these were selected Of the 12, 1 mother died, 1 developed a hemiplegia, 1 had a rheumatic recrudescence with associated heart-failure and 1 had pulmonary œdema post partum 2 babies were lost

We submit that this evidence does not invalidate our conclusion that, when a patient with mitral stenosis responds favourably to medical treatment, operation should be deferred until after delivery [9]

A BALANCED HOSPITAL COMMUNITY

SIR,—The ideas suggested by Professor McKeown (April 5) for a balanced hospital community are an admirable contribution to medical planning and development, but I wish that he had gone further still

His theme of centralising hospital buildings and administration to achieve a better and a wider service for the community can be applied with even more force to the National Health Service as a whole Just as the hospitals are at present dispersed and isolated, providing a limited service for selected groups of patients, so we have in the N H S a system whereby the three branches—hospitals, general practitioners, and public-health workers—are administered and organised by three separate and distinct

bodies (the hospital committee, the executive council, and the local authority) each working away on its own with no more than a superficial contact with the other two All three are concerned with promotion of health and the prevention and treatment of disease Surely it would be rational to expect them to be planned, organised, and administered as single units, working together in cooperation for a common cause

I should like to suggest that we think of the future in terms of such a unified health service administered by a common body for each area These areas could conveniently be the present hospital group regions with the main hospital in each area serving as the focal point for all three medical branches The hospitals, general practitioners, and public-health workers would then be organised from a single source and this should add to a mutual appreciation of each other's problems and lead to a more cooperative spirit in a more efficient service

Obituary

HECTOR CHARLES CAMERON

M A, M D Cantab, M A Glasg, F R C P

Dr Cameron, author of *The Nervous Child* and a pioneer of child guidance, died on April 1 in his 80th year The distinction of his mind and character, as well as of his work and writings, gave him much influence in pædiatrics, and he had a considerable share in its remarkable development

Son of Sir Hector Cameron, professor of clinical surgery at Glasgow, he went back to his native city when he left Clifton College, and took a Glasgow arts degree He then entered St John's College, Cambridge, as a foundation scholar in science, gained a first-class in the natural sciences tripos, and won a university scholarship at Guy's Hospital Qualifying in 1905, he was for a time demonstrator in physiology, and got the varied clinical experience obtainable in those days, combining at one time the appointments of medical registrar and tutor, assistant pathologist, physician to the nursing staff, and anæsthetist When he joined the Guy's honorary staff in 1911 he had been working as clinical assistant at the East London Hospital for Children and at the Evelina, and he decided to specialise in diseases of children Previously he had shown his literary bent as editor of the hospital gazette, and had already produced a succession of papers beginning with one on metastatic cerebral abscess, written with Mr W M Mollison, in *Guy's Hospital Reports* in 1907 His *Diet and Disease in Infancy* appeared in 1915 and the first edition of *The Nervous Child* in 1919 A master of the spoken as well as of the written word, he could tell a story supremely well, and his teaching, sometimes entertainingly acidulated, contained many of the sayings and anecdotes that stick in the mind

On bedwetting for instance, he said "Often the trouble with the enuretic child is not that he doesn't care but that he cares too much" And he told of a school where a housemaster wanted a boy expelled because he was a bedwetter "No", said the headmaster, "these are the boys who win scholarships"

Cameron was one of those doctors who have a really comprehensive approach to their patient's problem, considering not only the anatomical and biochemical disturbance but what is going on in his mind In consequence Guy's was the first teaching hospital to have, in 1931, a child-guidance department, and in the United States in the middle 1930s Cameron was by many regarded as the doyen or originator of the child psychiatry movement This was at a time when his teaching on these lines was largely ignored by his pædiatric colleagues

Outside his specialty, he did some regular life-assurance work which kept him in touch with the medicine of adults—though some felt sorry that he should have to divert any of his attention from the special subject to which he had so much to contribute Later, in years of retirement, he was able to make full use of his gifts as a historian

Such is the merest outline of a long and exceptionally fruitful life A clearer idea of his contributions to medicine, as thinker, clinician, and writer, is given by the following more personal tributes, the first from a senior, the second from a junior

Cameron belonged essentially to the older school of pædiatricians who depended for their results more on careful clinical observation than on laboratory reports He started his career with some initial advantages a family bias towards medicine, a fund of sound Scotch commonsense, a dry sense of humour, and—most important of all—a real love for children But the high position he reached in his chosen specialty was the result of steady hard work He first became known as a teacher at Guy's, and later to a wider circle, by his writings, for he was a ready writer and made many contributions to pædiatric literature Much the best known of these was his book on *The Nervous Child*, which is indeed almost a classic and is so delightfully written and contains so much sound sense and good advice that it can be put in the hands of even lay people interested in child guidance

Cameron was an ardent member of the British Pædiatric Association and one of his latest writings was a history of the Association published two or three years ago He rarely missed being present at the annual meeting of the B P A and was one of its most popular members, being admired by his fellows for his knowledge and beloved for his modesty and friendliness He will be much missed in the Association and indeed by the whole pædiatric world, but he has left an example in his character and work which should be an inspiration to those who follow him in the study and care of child health

R H

To pass down the Colonnade at Guy's for the first time and to cross the Park seemed to the university man in the early years of the present century only a familiar experience repeated, and when the Medical School had been gained, there awaited a welcome from a particularly charming don, the Dean himself This prepossessing person was Dr Hector Charles Cameron, a physician of Guy's and one of the men who upheld its fame, a pioneer in the art of medicine and a man of unsurpassed urbanity Though Cameron was well versed in scientific knowledge, he was more akin to a creative artist in mind By his power of perception he was able to apprehend the true and the beautiful, or in a word the good, by means of his imagination he related what he had perceived to human life, and the synthesis accomplished he gave expression to the idea through the art of medicine Out of such a philosophy, essentially Platonic, certain consequences must ensue The patient had to be seen as a whole, for health of mind and health of body are equally desirable and interdependent From that notion a practical psychology was formulated, which, less far-reaching than the modern variety, was a great deal more agreeable and wonderfully serviceable The bulk of this original doctrine he embodied in a book *The Nervous Child* which made his name known far and wide His ideas gradually shaped his career Having made a start as a general physician, as was the way, he found himself drawn towards mother and child, partly because they satisfy so well the aesthetic faculty, partly because they are plastic material, which holds out to the artist the promise of success Then, since an ideal conclusion is the business of our art as he conceived it, illness must be prevented as well as cured Finally, it would wrong him not to say plainly that a Platonic philosophy is an aspiration towards love Cameron was a true lover of his kind

-As a teacher he won great admiration He was always lucid, he never failed to interest, he had wit, wide reading and knowledge of the world, an easy eloquence and a polished style He charmed with his appearance and delightful courtesy, and with his artist's imagination he held his hearers The good that came from these ideal qualities was enhanced by two others not always their companions, industry to wit and practical ability It seems the natural thing today to gather the children into an outpatient department or house them in their own ward under the care of one who understands them, but Cameron had to accomplish these advances and was one of the first to do so Then with a fine stroke he founded a welfare centre in the precincts of the hospital Now only those who can set the child of forty years ago or more beside the handsome, happy creature of today can know what a revolution Cameron wrought, with others at his side

After his retirement he continued to exercise his pure and limpid prose *Joseph Lister the Friend of Man*, *Sir Joseph Banks the Autocrat of the Philosophers*, and his domestic history, *Mr Guy's Hospital*, are all valuable works He reached a hale old age, showing no alteration for years, and now that he is gone, it may seem commonplace to observe that he cannot be replaced Yet it is true, for the broad civilisation in which he was reared is being ousted by something very different *Damnosa quid non imminuit dies* ? But where he is concerned, who shall repine? He leaves the record of a fine vocation nobly fulfilled, great good accomplished, a blameless life and unswerving friendship

H St H V

Dr OLIVE STERN

R M. H writes

Olive Stern's background was richly cultural, which enhanced to the full her mental qualities She was incisive in expression and her construction was as fine as the finest rapier Naturally, this did not appeal to all, but to those who understood and appreciated it was just that diminutive creature who could smoke cigarettes, cigars, and a pipe and back her fancy in the Lincoln, Leger, National, and Derby She was spontaneously generous and one remembers with gratitude the hospitality extended in the delightful Old Billing home and later in Town " Petrol fumes " were the spice of life to her as they brought to mind her constant love—London—where with J G Greenfield, for whom she had a disciple's devotion, she was more than happy Her basic interest was neuropathology, but in general she was the vivid possessor of a tremendous wealth of detailed medical knowledge which proved invaluable to those who sought her opinion—and acted on it. Politically she was a bonny fighter and with the same undaunted courage she faced her final illness

SYLVANUS PERCIVAL VIVIAN

Kt, C B

Sir Sylvanus Vivian, formerly Registrar General, died on March 28 at the age of 77

In 1919 the General Register Office was brought within the province of the new Ministry of Health, and Vivian, who had worked in various departments of the Civil Service, was appointed Deputy Registrar General He succeeded Sir Berhard Mallet as Registrar General in 1921 and he supervised the census of England and Wales in that year and in 1931 His office was chiefly responsible for the compilation of the wartime National Register He was a member of the Boundary Commission in 1944 and retired in 1945, to be succeeded by Sir George North Outside his official life he had wide literary interests, and edited the works of Thomas Campion and contributed to encyclopædias

Notes and News

DIET AND HEART-DISEASE

The American Heart Association has issued to the public a leaflet on what is known and what is not known about the relation between diet and heart-disease It deals with fat, fads, sodium, and obesity—politely termed "overweight"

Readers are told that collections of fatty substances on the inside lining of the coronary arteries underlie most heart attacks, and that research is being done on whether changes in the diet can affect these, doctors may recommend low-fat or low-cholesterol diets in specific cases It is a mistake to listen to the tales of friends, relations, or popular magazines—"your health is much too precious to entrust to any person other than your doctor" Deposition of fat when more calories are absorbed than used is compared to piling up a bank account by depositing more than is withdrawn, but overweight, unlike a fat bank account, is not a good thing, because it adds to the work of the heart Sodium is essential to life, but its intake is sometimes restricted deliberately because in certain conditions it retains water in the body

The leaflet emphasises the importance of individual advice by a doctor in individual cases, it ends with five points to keep in mind—urging good general nutrition, efforts to keep weight normal, avoidance of special diets unless they are advised by a doctor, following a diet strictly where one has been prescribed, and asking a doctor's help about anything not understood

The Association's address is 44, East 23rd Street, New York 10, N Y, U S A

University of Cambridge

On March 22 the following degrees were conferred

M Chir—T W Rowntree, E J C Wynne
M B, B Chir—D E Side
M B—R C Dobbie (by proxy)

University of Birmingham

On July 5 the honorary degree of LL D is to be conferred on Dame Hilda Rose, a past president of the Royal College of Obstetricians and Gynæcologists, and the honorary degree of D SC on Prof A M B Lacassagne, director of the Radium Institute at the Pasteur Institute, Paris

Dr G H Thomas has been appointed senior lecturer in endocrine chemistry in the department of anatomy

University of Durham

On July 5 the honorary degree of D C L is to be conferred on Sir David Campbell, regius professor of materia medica and therapeutics in the University of Aberdeen and president of the General Medical Council

University of Leeds

At a recent examination O P Edmonds obtained the degree of M D

University of Dublin

The following have been awarded the diploma in gynæcology and obstetrics (D G O)

Mya Mya Aye, J O Toohey, F D Heelan, Khalida Abdul Wehab Al Kayssi, *J D Le Souef, Shalini Tanavde*

Royal College of Physicians of Ireland

On March 28 the following were granted the licence in medicine and midwifery

J G Bailie, Efiong Ekpo, J R McClean, Frances M U Power, Subhan Ally Ramjanally, R F Rampersad, J D Rautenbach, Ewa Wohnout

Royal College of Obstetricians and Gynæcologists

On Friday, May 30, at 5 P M, at the college, 58, Queen Anne Street, London, W 1, Mr J S Scott will give a William Blair-Bell lecture on pregnancy toxæmia associated with hydrops fœtalis, hydatidiform mole, and hydramnios Admission is by ticket which may be had from the secretary of the college

Central Midwives Board for Scotland

The medical members of the reconstituted board are as follows

Mr J Bruce Dewar (Dumfries), Prof David McKay Hart (Glasgow), Dr Catherine Harrower (Glasgow), Prof R A Lennie (Glasgow), and Dr Nora Wattie (Glasgow)

South West Metropolitan Regional Hospital Board

The following have been awarded prizes in the board's 1957 competition

Consultants and S H M Os—Dr A A Cunningham and Dr J Towers
Senior registrars, registrars and J H M Os—Mr J C Gazet, Dr A J Taylor, Mr P W Seargeant, Dr J R H Pinkerton, and Dr P Farnan
Senior house officers—No entries received

Notice of entry for this year's competition (with proposed subject) should be sent to the board's senior administrative medical officer (Gen /CST) by Sept 30, and reports must reach him by Dec 31

British Association of Pædiatric Surgeons

The annual meeting of this association will be held in London from July 23 to 25 On Wednesday, July 23, at 5 30 P M, Dr Willis Potts, from Chicago, will give the Simpson-Smith lecture on tracheoœsophageal fistula with and without atresia, and on Friday, July 25, at 4 30 P M the Moynihan lecture on respiratory emergencies in the newborn Further particulars may be had from Mr R B Zachary, The Children's Hospital, Sheffield, 10

Royal Commission on Remuneration

The Royal Commission on Doctors' and Dentists' Remuneration will hold a public hearing on Thursday, April 17, at 10, Carlton House Terrace, London, S W 1 Representatives of the Ministry of Health, the Department of Health for Scotland, and the Treasury have been invited to attend The hearing will begin at 11 15 A M and is likely to continue into the following day

Industrial Health and Accident Prevention

A conference on this subject, organised by the Industrial Welfare Society with the support of the Scottish Industrial Groups Advisory Council and the Association of Industrial Medical Officers, will be held at the St Enoch Hotel, Glasgow, on April 30 The speakers will include Dr Andrew Meiklejohn, Dr J H Bell, and Dr A Girdwood Fergusson

Portrait of Sir Alexander Fleming

On March 26 at St Mary's Hospital, London, Prof C A Pannett unveiled a portrait of the late Sir Alexander Fleming, by Miss Anna Zinkeisen, which is to hang in the boardroom of the hospital It was remarkable, he said, that though St Mary's is little more than a hundred years old and has possessed scientific laboratories for only a fraction of that time, already two workers in those laboratories have attained imperishable fame, and both by saving countless human lives—Almroth Wright by his invention of anti-typhoid inoculation and Alexander Fleming by his discovery of penicillin To those who knew them it was a sad and chastening thought that to neither had been raised a great scientific institute, nor had there been created, as a tribute to their memory, a scientific foundation in any way commensurate with the benefits they had conferred on the hospital and the world The same treatment had been handed out to Jenner, and it was typical of the English indifference to great men and particularly to the humble scientist However, this portrait, commissioned by the governing board, was impressive and successful, a superb piece of craftsmanship, and as Sir Alexander gazed down on the members in their deliberations, they would be aware of the greatness of St Mary's and the nobility of their task

---

On *Monday, April 14, at 7 30 P M at 5, Old Burlington Street, London, W 1, the Society for Visiting Scientists will hold a meeting* on Personality The speakers will be Prof Marc Klein, of Strasbourg, Dr W Mays, and Dr J D Sutherland

A meeting of the Naval Medical Compassionate Fund will be held at 2 30 P M on Friday, May 2, at the Medical Department of the Navy, Queen Anne's Mansions, St James's Park, London, S W 1, to elect six directors of the Fund

The first volume of the new edition of the *Manual of the International Statistical Classification of Diseases, Injuries, and Causes of Death* appeared last October (see *Lancet*, 1957, ii, 882) and came into force at the beginning of this year The second volume, an alphabetical index, has now appeared, and is obtainable from H M Stationery Office The two volumes together cost 35s

The Lancet · Saturday 19 April 1958

ADMINISTRATIVE THERAPY
ITS CLINICAL IMPORTANCE IN THE MENTAL HOSPITAL *

D H CLARK
M A Cantab, M B Edin, M R C P.E, D.P M
MEDICAL SUPERINTENDENT, FULBOURN HOSPITAL, CAMBRIDGE

PSYCHIATRY today is becoming steadily more specialised, and the day of the old-time medical superintendent who was master of all possible trades within the asylum has passed. He was at once senior psychiatrist, consultant physician, medicolegal expert, morbid pathologist, and general practitioner to the resident staff. Today no-one is called upon to exercise all these skills, and there is a chance to examine afresh the work and role of the medical superintendent and see what therapeutic possibilities they offer. From my attempt to study this I have emerged with a concept of Administrative Therapy—the art (perhaps some day to be a science) of treating psychiatric patients in a mental hospital by administrative action. Group therapy developed from individual therapy, administrative therapy is treatment of a much larger group, the hospital. It draws on the knowledge and skills of psychiatry and group psychotherapy, the experience of the professional administrators, and the accumulating contributions of the social anthropologists.

The Administrative Role

What does the role of medical superintendent mean to the doctor who undertakes it? What limitations and obligations does it place on him? Every psychiatrist cherishes a fantasy of what he would do if he were medical superintendent of his hospital, the essence of this fantasy is the delusion that the medical superintendent is omnipotent and can do anything he wishes. A doctor who becomes medical superintendent soon finds out how limited he is, there are so many things that he cannot do or that take a long, long time. There are the obvious limitations which block his programme—shortage of money, ancient buildings, overcrowded wards, shortage of nurses, not enough doctors, conservatism of those long in office, limitations of Treasury finance, and the tremendous difficulty (in the complex organisation of the National Health Service) of getting any new idea accepted. All these things are well known and understood. Underlying them all is the inertia of any large human organisation, which is the sum of the unwillingness of many people to change their ways.

More limiting than the things he cannot do, however, are the things he must do. Every administrator must carry out a number of ritual public actions which can be performed by no-one else, they may be disturbing, frustrating, or merely boring, but he must do them. It is in this context that the word "role" which we use so glibly approximates most closely to its theatrical meaning, for the leader of any organisation has to perform certain acts which are prescribed for him and for which he may personally have little taste. He is the figurehead, the spokesman, and at times the voice of conscience, these duties take up time which he often feels to be wasted, for they give him no feeling of achievement and certainly none of "proper work."

As figurehead he must function on public occasions, making speeches, setting forth the principles of the organisation, proposing votes of thanks graciously, he must offer public congratulations, he must make presentations to the employees who have been a long time in the hospital, he must speak at nurses' days and at the opening of new buildings. At all these times he must express the feelings of the staff and the patients and yet at the same time draw out unifying themes and suggest future goals. He must act as chairman of certain essential coordinating committees within the hospital, where departments are in conflict and only he can mediate. It is only reasonable to hand over some of these tasks to others, but he must beware how often he does this, he must remember that there is always a loss of definition when he does.

There are aspects of the role which may be frankly repugnant, especially to a sensitive psychotherapist. Promotion must be made, every time one person is gratified by promotion several are dissatisfied or even embittered. When someone breaks the rules, the administrator must not shirk the unpleasant duty of seeing the errant offender, cautioning him, and if necessary discharging him. Much can be done to obviate social disturbance by fair dealing, by constant self-scrutiny, and by willingness to admit mistakes, but there comes a time when someone must pronounce the community disapproval of an individual's actions, and the leader of the community forfeits its confidence and weakens it if he is not prepared to do this.

The administrator should not actively seek transgressors, seeking transgressors is an antitherapeutic activity best left to those whose task it is, such as auditors. If communications are free, malpractices soon come to light, if an irregular procedure gives no-one cause for complaint, then there is little need to seek it out. If an administrator spends his time checking his juniors, he conforms to the traditional asylum stereotype of fault-finding authority and soon paralyses the hospital. His task is the more difficult one of seeking out and encouraging initiative and therapeutic development.

The doctor who becomes medical superintendent will learn some of the lessons and pains of administration. He will find folklore and fantasy condensing about him whatever he does, so that he will be credited by some with magical prescience and wisdom, and by others with malignant cruelty and foolishness. He will find injustice and even tyranny exacted in his name. He will learn the gratification of seeing a change, long fought for, produce the desired result, and the bitterness of espousing and effecting a change only to see it fail because of flaws he had not perceived. He will learn how long it takes to bring about a change, how change imposed is of little value, how patience and a sense of timing often achieve more than enthusiasm.

The role of medical superintendent, like every other worth-while role in life, will have a moulding effect on him. To the characteristics developed by years of medical responsibility will be added characteristics of the wielder of power—the cautious utterance, the guarded promise, the ready excuse that saves the need of self-scrutiny, the specious justification, the growing pomposity and intolerance of criticism, the diminution of scientific detachment. All these will come, and his friends and colleagues will commiserate with his wife as they become more obvious.

Medical or Lay?

These are some of the experiences and problems that face any administrator. Is a doctor, a psychiatrist, the person to undertake them? Administration of general hospitals is carried out by non-medical professionals in England (though not in Scotland), some of them have

---

* Based on an address to the psychotherapy and social-psychiatry section of the Royal Medico-Psychological Association on Oct. 9, 1957

pressed strongly that the mental hospitals would also be better out of the hands of the doctors—though they state this as an altruistic desire to "free the doctors for their proper work" The debate often reaches a high pitch of acrimony as the well-organised and vocal groups battle for privilege and power, many of the arguments are specious, transparently self-interested, and valueless except as debating points But the question must be considered A bad administrator is a disaster for any hospital, be he medical or lay—and examples of both are easy to find in English hospitals Their faults are different but equally pernicious The bad lay administrator is a petty-minded bureaucrat, ruled by regulations, frightened of responsibility, and insensitive to human needs, the bad medical administrator is a patient-centred doctor who regards administration with contempt, who lacks the ability to plan and think ahead, the courage to face group situations, and the imagination to understand the problems of non-medical professional groups

Any doctor who undertakes to be an administrator must accept what that means He must be prepared to learn something of administration, he must have an interest and ability in handling, leading, and uniting people He must be tolerant of the status systems of professions other than his own, and understand that coming in by the front door, or wearing a collar, may mean as much to someone as the right to a long white coat once did to him He must learn a smattering of many jargons He must lend an interested ear to the catering officer, the engineer, and the garden manager, and must understand what pains them He must, too, be ready to think seriously about the structure of authority and organisation, it is not enough to rely on traditional modes of direction

Doctors do not generally make very good administrators All their training has been away from this, and if a doctor is a good administrator it is because a talent for handling groups and an interest in working with them has survived his medical training Throughout the medical training, skill is developed towards a two-person situation, and a very special two-person situation—the handling of a patient who is often socially and intellectually inferior to the doctor, and, if he is not, is unmanned by anxiety, pain, and fear of death The doctor is the expert whose words are weighty and powerful, his verdict is the utterance of a judge The psychiatrist and the psychotherapist are further trained to think of the individual patient and his good, but seldom of the good of the community or the group

The doctor with experience of group or social therapy comes to administration with an advantage He has learnt to think in terms of the group rather than the individual, he has already begun to swing away from the exclusive one-patient orientation of the traditional doctor and traditional psychotherapist This is of great value when he comes to administration, where every decision has to take into account the needs of a number of individuals In his group therapy he has acquired an ability to handle the group situation, which again is valuable Many medical superintendents never acquire this when they are alone with a patient or with a junior doctor they are competent and powerful, when faced by a group they become anxious, secretive, and fear-ridden A group therapist, however, should have worked through this He can sit among a dozen other people, watch what they are doing, listen to what they are saying, and contain the anxiety that arises in him when heavy hostility or pressure is directed against him, he can feel what is happening, engage in the interaction, and yet keep sufficiently apart to observe it and wait his time for joining in

The psychiatric administrator has to take part in one group which is an entirely new experience to him—the management committee Here he is not the leader, the therapist doctor, the omnipotent expert, he is not even a member of the committee, he has no power to vote, he is merely an official The determination of policy is in the hands of the committee

This role comes hard to doctors, for they are accustomed to being experts, and the experience of working with lay committees can be peculiarly disturbing for them Perhaps for the first time since he entered medical school the doctor meets laity who may not be much impressed by his statements and can say so, who do not credit him with omniscience Those fascinating and admirable people who give constant and assiduous voluntary service on committees have limited respect for experts of any kind, including doctors They themselves are magistrates, town councillors, and aldermen, accustomed to judge the affairs of their fellow men and make decisions affecting the lives of others They have often heard experts explain with specious technical jargon why certain courses must be followed, and they are no longer to be taken in They have seen through borough surveyors, have deflated headmasters, and have goaded medical officers of health into action, they are little impressed by oracular certainties If the medical superintendent wishes to carry the management committee with him he must learn to justify his policies on sound well-based grounds of the general good They will allow the doctor his full meed of expert knowledge but if he wishes to spend more public money, he must show good reason why

The Fabric of Human Relations

The third report of the World Health Organisation's Expert Committee on Mental Health[1] said that the most important single factor in the efficacy of the treatment given in a mental hospital is "an intangible element which can only be described as its atmosphere" They gave in detail some of the elements which make up that atmosphere, and went on to say

> "As in the community at large, one of the most characteristic aspects of the psychiatric hospital is the type of relationship between people that are to be found within it, the nature of the relationships between the Medical Director and his staff will be reflected in the relationships between the psychiatric staff and the nurses and finally in the relationship not only between the nurses and the patients but between the patients themselves"

This is a challenging statement, and contains the kernel of administrative therapy—which may be defined as the manipulation, modification, and constant scrutiny of the relationships spreading out from the administrator, with the aim of controlling their effect on the patients

Administrative therapy is in much the same state as psychotherapy was in the 1880s At that time many doctors, neurologists, and alienists were talking to patients about their lives and their problems and helping them, some were exhorting patients to follow different modes of behaviour and by that exhortation were improving their adjustment to life There was, however, no awareness of what they were doing, no insight into the factors concerned, and such instructions as they gave were based on self-evident principles. Then Freud showed how much more went on between the doctor and the patient, and interpersonal reactions began to be explored. After fifty years we are now at last beginning to understand something of the dynamics of the two-person therapeutic situation. Administrators at present tend to handle their organisations with as much insight as Charcot used with his hysterics, they proceed from intuition, self-evident deductions, and political theory, their only guide being catchwords and slogans. We need to study how actions and activities of the administrators finally affect the patients, and (more important) learn how to alter these actions therapeutically. In this way we shall develop some knowledge of administrative therapy.

---

[1] World Health Organisation Third report of the Expert Committee on Mental Health Geneva, 1953

The fathers of institutional psychiatry had no doubt in their minds about the importance of administrative therapy though they called it "moral management". One has only to read Tuke's *Description of the Retreat*[2] or Pinel's *Treatise on Insanity*[3] to see the importance they give to the management of the house, both stressed how unimportant formal medicine is and how useless drugs, bleeding, and purgation. Both of them discussed with admiration the work of the men who ran their hospitals, Pinel rapturised about Pussin, Tuke soberly praised the skill and consideration of Jepson, both devoted large sections in their books to describing just how the asylum should be organised and the rules that should be laid down for the life of the patients.

In each generation reformers arose, like Kirkbride in America and Simon in Germany, who restated some of the principles, occasionally with an individual twist of their own, they were heard for a time, and then they were forgotten and dropped away. The W.H.O. report sets out the principles yet again, and they are very similar to those of Tuke and Pinel. Patients are to be trusted and given as much freedom and responsibility as possible, their individualities must be preserved, and the life in hospital made as much like that outside as possible, particularly by providing regular planned and sustained activity and employment.

Four Principles

When a psychiatrist decides to become a medical superintendent how can he look at his job? What are the principles that he is to follow? There are four main facets of administrative therapy:

1. Organisation of the patient's life.
2. Staff organisation.
3. Medical organisation.
4. Community leadership.

These are, of course, interlinked, and maladroitness in one affects the others, but they are in some degree separate. Of every action one must ask the dynamic questions. How was it done? Did it have the effect desired? What other side-effects did it have? Did it help the patients?

Patient's Life

The first is perhaps the easiest of the four, for a great deal is known about it. The ideas of moral treatment and the principles put forward by the W.H.O. report give a start. It would take several years' work in any hospital to get these accepted as a fundamental way of life. The abolition of restraint, seclusion, locked doors, and over-sedation is the first move. Proper segregation into wards each with a definite function is of great value. Diligent organisation of a full work therapy programme for all patients in the hospital takes time and it must include a proper system of rewards and payments. These first essentials can be fairly easily achieved over a few years, though a close guard must be kept against the custodialism which is forever creeping back under the guise of economy and "efficiency". Next comes the development of self-government for the patients and experiments in communal living—group therapy, discussion groups, play-reading, hospital magazines, and mixed units.

Staff Organisation

To organise a therapeutic staff is more difficult. The staff in any mental hospital has been trained for years in custodial attitudes, they were trained to count patients and to watch stock, they learnt that an escape was the most awful sin—worse even than a suicide or an accident—and they have acquired whole series of custodial and often punitive reflexes that are not easily abandoned. In most hospitals, too, there is a rigid hierarchial system with orders passed down from above and a severe blockage on the flow of information upwards, there are usually rigid status barriers between the different categories of staff. The administrative therapist must decide what to tackle first. He cannot just plunge in naïvely with the ideas of making everybody democratic, if he endangers the security of senior staff, he himself may be extruded.

The emphasis should be first on communication. Meetings should be held with various groups of staff and they should be encouraged to bring forward ideas, through such meetings new channels of communication can be laid down. It is a grave mistake to come to the conclusion that some person or other is nothing but a bar to all progress and to attempt to "drive him out". If your patients are to have human dignity, your staff must have it too. The only correct assumption is that everyone has something to contribute and that given the chance he will do his best.

Questions of responsibility and authority are central and must be constantly studied. In most mental hospitals there is scope for far wider devolution of responsibility.

Medical Organisation

The administrative therapist must give special thought to the organisation of the doctors. They may have little interest in his abilities as a social therapist, but they wish to believe that he can practise their art of clinical psychiatry at least moderately well. The medical superintendent should continue to see his own cases and have cases within the wards, otherwise he will no longer understand his colleagues' problems. The relations of the administrative therapist with the consultant psychiatrists are a difficult and testing point. At present there is much pain and bitterness about this in English mental hospitals. Some medical superintendents still think in terms of the pre-1948 situation, when the medical superintendent was personally responsible for the treatment of every patient. Today the consultant psychiatrist has full responsibility before the Law and before society for the treatment of his patients, and there can be no excuse for the medical superintendent interfering in the treatment prescribed. But the issue goes deeper. The consultant psychiatrists are the only group of peers whom the medical superintendent meets, the only group who share his professional training. Many consultant psychiatrists despise administration and do not think much of administrative therapy or social psychiatry. What they want to do is to treat individual patients in the one-doctor/one-patient relationship, this they think of as the highest good. The administrative therapist's task is to provide a milieu in which everyone may do his chosen job to the best of his ability without interference, and this is as true of the consultant psychiatrist as of humbler people in the organisation. If an administrative therapist does his own job well and takes the same care to avoid trespassing on another doctor's patients that is standard throughout medicine, his relations with his consultant staff should be good. If he can provide them with the facilities they need to do their work, free of the more vexatious hospital irritations, he will gain their gratitude and respect.

---

[2] Tuke, S. A Description of the Retreat. York, 1813.
[3] Pinel, P. A Treatise on Insanity. London, 1806.

The medical organisation will vary with the size of the hospital It has been suggested that the best size of unit for administrative therapy is about 300 beds, it is still just possible to administer 1000 beds as a unit With larger hospitals, however, the span becomes too great and it is necessary to split the hospital into “ firms ” running self-contained units with a consultant and senior nursing officer in charge The only difficulty with this is that differing cultures develop in the self-contained units, if they differ too much, it is hard for patients and junior nurses to understand that one institution can have such different units within it, and they may find the passage awkward from a liberal environment to a restrictive one

Community Leadership

If any human organisation is to work well, it should have confidence in itself, it should have a policy, and it should have good morale The administrative therapist must give these to the hospital as best he can The hospital policy must be clearly formulated In the past the cries have been “ non-restraint ” and “ full activity ”, recently it has been “ open doors ” The policies of the W H O report must be worked into the structure of the hospital and embodied in slogans which can be understood by the most uninterested staff member They must be repeated again and again until they really have meaning and until the words “ therapeutic community ” mean not just the bee in the superintendent's bonnet but a way of living and acting

Relations upward are always difficult, and it is in this sphere that some social therapists fail sadly, while some autocratic medical superintendents have often been quite successful The hospital management committee decide the policy of the hospital, if an administrative therapist is going to change the whole life and way of a hospital he must carry the management committee with him They are mature and tend to conservatism, they are dubious about the enthusiasms of youth and many have much previous experience of the hospital They must be won to new policies which must be put to them in terms of the humanitarian gain to the patient, for in this they are always interested Beyond them the policy must be carried to the public, it is no use opening your doors if the local public and the police shout to have them locked again In this the cooperation of the local press is vital and the administrative therapist must work with them Cheerful reports about the hospital will dispel criticism, will build up the morale of the staff, and will do much to allay public anxieties

In an N H S Setting

Within the National Health Service there is constant work to do Though new buildings do not produce good psychiatric treatment, some new equipment is needed for the hospital, and the hospital which feels that it gets the last handout of everything may become dispirited The administrative therapist as leader of the hospital and spokesman for its policy must be prepared to argue policy up the various tiers of the National Health Service, this involves knowledge of local power relationships and a willingness to explain again and again things which seem crystal clear It needs patience and self-control to put over an idea, which is of great personal importance, to a committee who are perhaps uninterested or committed to the needs of another hospital, and to carry conviction so that the needed money is granted

There is also a constant defensive battle to be fought, ever busy within the fabric of the National Health Service are those white ants, the auditors, nibbling away and eroding the fabric of human relations and good feeling They are employed to peer through every hospital attempting to prove that everyone is dishonest and that no-one can be trusted, given their way they would multiply the regulations until the hospital was bound in a cocoon of red-tape, all in the name of “ efficiency ” They must be watched unceasingly and every claimed advance in efficiency scrutinised with great care to see it does not harm the human relations of the hospital Luckily they too are only servants, and the masters are the hospital management committee, the representatives of the public, if an administrative therapist is worth his salt he can carry the point against the auditors and show that the welfare of the patients and the trust and happiness of the staff are first essentials

But the most important task of the administrative therapist is to establish the atmosphere of the hospital And this, the most important, is the task most difficult to describe He needs openness, consistency, respect for everyone's human dignity, and a welcome for everyone's contribution, a belief that everyone wishes to help and that no-one is past recovery—neither the most demented patient nor the most stupid nurse For one thing is certain as he treats his staff so will they treat the patients

* * *

These are some of the aspects and personal meanings of the art of Administrative Therapy as they strike one new to the field, but there is so much to learn Studies like those of Stanton and Schwartz[4] point the way to an understanding of the dynamics and the effects of administrative action By such means, knowledge may gradually replace intuition until the art becomes a science

THE AUTOANTIBODY NATURE OF THE THYROIDITIS ANTIBODY AND THE ROLE OF THYROGLOBULIN IN THE REACTION

ERNEST WITEBSKY
M D
DISTINGUISHED PROFESSOR OF BACTERIOLOGY AND IMMUNOLOGY

NOEL R ROSE
Ph D
ASSISTANT PROFESSOR OF BACTERIOLOGY AND IMMUNOLOGY

SIDNEY SHULMAN
Ph D
ASSISTANT PROFESSOR OF IMMUNOCHEMISTRY

From the Department of Bacteriology and Immunology, University of Buffalo School of Medicine, and the Buffalo General Hospital, Buffalo, New York

In rabbits, dogs, and guineapigs, intradermal injection of thyroid extract (combined with Freund adjuvants) from other animals of the same species engenders the production of organ-specific thyroid antibodies, as well as an accompanying thyroiditis (Witebsky and Rose 1956, Rose and Witebsky 1956, Witebsky et al 1956) An extract of the animal's own thyroid gland has the same effects Moreover, the serum of some patients with chronic non-infectious thyroiditis contains a factor that reacts with human thyroid extract, normal or goitrous (Roitt et al 1956, Witebsky et al 1957, Paine et al 1957, Doniach and Roitt 1957) On the basis of the animal experiments, it has been proposed that this serum factor is a true autoantibody, and that the pathogenesis of the clinical disease is related to autoimmunisation Additional evidence for the autoantibody nature of the serum factor is found in experiments in which thyroid extracts from numerous different individuals exhibited essentially identical titres when tested with a thyroiditis serum (Witebsky 1957) The criteria for establishing the existence of antoantibodies have been discussed by us previously (Witebsky et al 1957)

---

[4] Stanton, A , Schwartz, M The Mental Hospital London 1955

TABLE I—RESULTS OF TANNED-CELL HÆMAGGLUTINATION TEST

Dilutions of Buc serum	Tannic-acid-treated human erythrocytes (group O) coated with saline extract* of	
	Buc. goitre	Het. goitre
1 20	+++†	+++
1 40	++	+++
1 80	++	++
1 160	++	++
1 320	++	++
1 640	±	±
1 1280	±	–
1 2560	–	–
control‡	–	–

* Each extract diluted 1 100 and immersed in boiling water for 2 minutes

† +++ to – indicates various degrees of agglutination of erythrocytes after tubes were allowed to stand overnight at 4°C.

‡ Tanned but uncoated cells Other controls using normal human sera rather than patient s serum were uniformly negative.

Nevertheless, as Cruickshank et al (1957) have emphasised, an important step in establishing the presence of a true autoantibody (rather than an isoantibody) is the demonstration of a reaction with the patient's own tissues Mackay, Larkin, and Burnet (1957) have pointed to the failure of certain so-called autoimmune antibodies to react with antigens prepared from the individual's own tissues We therefore report here an experiment illustrating just such an in-vitro reaction

Observations

A patient, Mrs Buc, was operated on at the Buffalo General Hospital in October, 1956, when a large diffuse colloid goitre was removed A sample of her serum taken at this time (Oct 23, 1956), when examined by the tanned-cell hæmagglutination and precipitation methods, revealed no trace of thyroid antibodies The surgically removed tissue was stored in the frozen state.

Taken four months later (March 15, 1957), a second sample of her serum produced a positive reaction in the tanned-cell hæmagglutination test for thyroid antibodies (titre 700) using pooled normal human thyroid extracts as antigen Precipitation tests were negative (A sample of her serum, taken in December, 1957, revealed a slight decrease in antibody titre—500) The possible clinical significance of the postoperative appearance of antibodies in this case has been discussed by Paine et al (1957)

The patient's thyroid tissue obtained previously was thawed, and a saline extract was prepared by our usual technique A similar extract was prepared from a second surgically removed non-toxic goitre (Het), and both goitre extracts were used as antigens in a tanned-cell hæmagglutination test of a sample of Buc serum The results of the test are given in table I, which shows that the patient's serum agglutinated human erythrocytes coated with an extract of her own goitre as well as the goitre extract of another person, Het The titres in each case are the same within experimental variation, and resemble those obtained in other experiments with a pool of thyroid extracts

TABLE II—ULTRACENTRIFUGAL ANALYSIS OF PATIENT'S THYROID EXTRACT AND FRACTIONS

Fraction	Concentration (total protein) (g per 100ml.)	Peak	Analysis (%)	Total thyroglobulin (g per 100 ml)
Initial saline extract	4·07	I	4·51	
		II	52·4	2 13
		III	1 53	
		IV+V	41·5	
P 1 60–1 70* (' thyroglobulin)	2 48	I	2·45	
		II	94 6	2 23
		IV+V	2 99	
P 1 70–4·00†	1·93			
RP 2·50–3·00 (thyralbumin)	1 16	V	100·0	

* Precipitate obtained between 1·60 and 1 70 M ammonium sulphate.

† Residual proteins after precipitation of thyroglobulin fraction.

We conclude, therefore, that the thyroid antigen involved was actually present in the tissues of the patient, as well as in the thyroid glands of other persons

Discussion

Which constituent of the thyroid extract is responsible for the reaction observed? Our preceding investigations (Witebsky et al 1955, Rose and Witebsky 1955, Shulman et al 1955) on the organ-specific nature of thyroglobulin suggested to us that, in animals, it would play the leading role in autoimmunisation Similarly, Roitt, Doniach, Campbell, and Hudson (1956) have regarded thyroglobulin as the important antigen in human thyroiditis To study this point further, the Buc extract was fractionated by addition of ammonium sulphate in the same manner as previously described for hog-thyroid extract (Shulman 1956, Shulman et al 1957) Ultracentrifugal analysis of the initial saline extract revealed at least five sedimenting components (table II), of which one, peak II, was identified with the classical thyroglobulin on the basis of its sedimentation constant These sedimenting components seem to be completely analogous to those observed in hog preparations (Shulman et al 1955, Witebsky et al 1956) The portion of thyroid extract precipitating between 1 60 and 1 70 M ammonium sulphate shows a relative enrichment in thyroglobulin content and a considerable decrease in content of peaks I, III, IV, and V The only other ultracentrifugal component available in purified form is peak V, the thyralbumin fraction, obtained by precipitation between 2 50 and 3 00 M ammonium sulphate (Shulman et al 1957)

TABLE III—INHIBITION OF PATIENT'S SERUM BY VARIOUS THYROID FRACTIONS

Fractions of Buc thyroid	Antigen dilution
Initial saline extract	1 128 000
P 1 60–1 70 (thyroglobulin)	1 64,000
Residual supernatant (P 1 70–4 00)	1 4000
P 2 50–3·00 (' thyralbumin ')	1 80
Norman human kidney extract	0*

* No inhibition with undiluted extract

To measure the antigen content of the various thyroid fractions agglutination-inhibition tests were set up Serial dilutions of each fraction were prepared and added to aliquots of the Buc serum diluted to contain about four (2+) hæmagglutination doses After an hour at room temperature tanned human red cells coated with the Buc thyroid extract were added to each tube, and the degree of agglutination was read in the usual way

Table III shows the highest dilution of each thyroid component capable of completely inhibiting agglutination The initial saline extract, as well as the thyroglobulin fraction, can neutralise the reaction of Buc serum in high dilutions and are almost equally effective The thyralbumin fraction and the supernatant from the thyroglobulin precipitation show relatively little activity

These findings suggest that the antigen involved in the autoimmunisation leading to thyroiditis precipitates in the thyroglobulin fraction, and that this antigen can elicit demonstrable circulating antibodies in the same individual

We wish to acknowledge the capable technical assistance of Miss Dolores Floss and Miss Helen Sturzebecker The work was supported in part by grant C-2357 from the National Cancer Institute.

PRE-EPIDEMIC ANTIBODY AGAINST 1957 STRAIN OF ASIATIC INFLUENZA

IN SERUM OF OLDER PEOPLE LIVING IN THE NETHERLANDS

J Mulder
M D
PROFESSOR OF MEDICINE IN THE UNIVERSITY OF LEYDEN, HOLLAND

N Masurel
BACTERIOLOGIST

With the technical assistance of Miss E M Deggars *and* Mr P J Webbers

After a strain of Asiatic influenza (A/Asia/Singapore/1/57) had been received by us at the end of May, 1957, from Dr C H Andrewes, of the National Institute of Medical Research, London, it soon became clear, using ferret antisera, that there was no cross-overlapping of surface hæmagglutinins between the egg line of this strain and the ferret-mouse-egg lines, egg lines, and egg-mouse-egg-lines of human A strains isolated in 1933–56 or a strain of swine influenza (Swine/15) isolated by Shope (1931) Similar observations were made by Meyer et al (1957), Jensen (1957), and Dr A Isaacs, of the National Institute of Medical Research, London (personal communication) Later it was shown that the same holds true for the mouse-lung-adapted line of the Asiatic strain

When, however, a few paired sera from patients who had had influenza in 1953 were tested against the Asiatic strain, one hæmagglutination-inhibiting titre of 44 was found in a serum taken during the acute phase of the disease in a patient aged 88 Next, of 12 sera from persons aged 59–84 2 from persons aged 80 and 84 showed a positive titre

With the aid of many doctors in the Netherlands we collected in June as many sera as possible from people aged 50–100 We already had in our laboratory sera from the younger age-groups Altogether 1256 sera were collected and stored at −20°C Through Dr A M M Payne, chief of the Section of Endemo-Epidemic Diseases of the World Health Organisation at Geneva, other laboratories in the world were asked to collaborate in this investigation and to collect sera as soon as possible before the Asiatic influenza had spread into their country In the Netherlands we were just in time, because the epidemic in this country started with its first focus in the middle of June

Methods and Materials

Hæmagglutination-inhibition (H I) Test

Sera were examined individually for H I antibody against the strain A/Asia/Japan/305/1957 (passage formula egg_x-ferret_3-mouse_6-egg_n) obtained from Dr K Jensen In our experience this is a more sensitive strain for this purpose than the egg-line of the strain A/Asia/Singapore/1/57 (Dr K Jensen, personal communication)

The titres of positive sera are expressed as the *reciprocal* of the dilution of the serum interacting with the virus and giving 50% hæmagglutination, being finally corrected to the use of 3 agglutinating units (A U) of the virus The non-specific inhibition of the sera was abolished by the use of enzymes of *Vibrio choleræ* (see Brans et al 1953)

After the screening of the sera had been finished, all the positive specimens were re-examined on the same day by two different workers The final H I titre was considered to be the arithmetical mean of the titres obtained in both tests Usually the titres in this final control did not differ substantially from those obtained in the screening test, the only exception being a few very low titres which in the final test proved negative Low titres were read with great care because pattern formation in low dilutions of sera not containing H I antibody may be incomplete

After the investigation had been finished, the ages of most of the people aged 70–100 who showed a positive H I titre were checked

Mouse-protection (M P) Test

In the M P test the strain A/Asia/Ned /43/57 (passage formula mouse_{22}-egg_{1-4}) was used This strain is identical with A/Asia/Japan/305/57 in the cross-H I test From the emulsion of infective mouse lung of the 22nd passage the strain was grown in the allantoic cavity of the chick embryo, and the egg fluid was used in the M P test The advantages of this method are that constant amounts of virus can be used in the different tests, and that the virulence of the virus can be maintained more or less constant M L D of about either 50 or 5 were used according to the H I titre of human serum, because usually H I titres below 30 could only be confirmed as true antibody in the M P test when fluids of low virulence were used

TABLE I—INCIDENCE OF PRE-EPIDEMIC POSITIVE H I TITRES IN HUMAN SERA OF DIFFERENT AGE-GROUPS AGAINST INFLUENZA STRAIN—A/JAPAN/305/57

Age-group (yr)	No of sera	No giving positive H I test
1–9	11	0
10–19	30	0
20–29	72	0
30–39	85	1 *(1 2%)*
40–49	121	2 *(1 7%)*
50–59	163	2 *(1 2%)*
60–69	361	4 *(1 1%)*
70–79	280	14 *(5 0%)*
80–89	122	27 *(22 0%)*
99–100	11	2 *(18 0%)*
Total	1256	52

We used as control sera in each experiment homologous ferret antiserum and the sera of two persons aged 24 containing antibodies against many former human A strains except the Asiatic strain In a second experiment it was shown that neither high-titred ferret antisera against the influenza strain A/Swine/15 nor against the egg- and mouse-lines of all the main types of former human influenza-A strains protected mice against infection with the Asiatic strain Six mice were used per dilution of serum, but in most of the experiments only the serum dilution 1 2 was used Necropsy on surviving mice was done 7–10 days after inoculation, according to the number of M L D used in the experiment

Complement-fixation (C F) Test with Soluble Antigen of Influenza Virus A

This test was made according to Hoyle (1948), egg-membranes being used for preparing the antigen

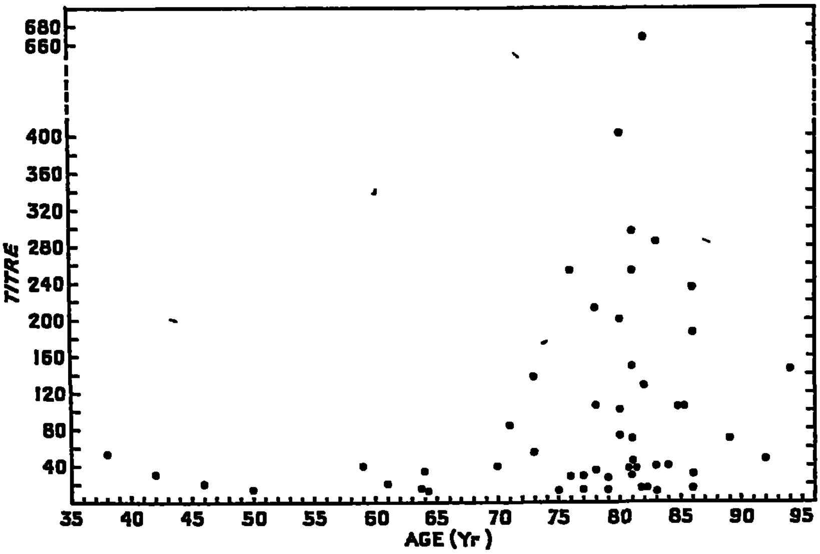

Fig 1—Age-distribution and positive H.I. antibody titre against influenza strain A/Asia/Japan/305/57 found in 1256 normal sera collected in Holland before July, 1957 (titres of <8 not incorporated)

Results

Positive H I titres were found in 52 of the 1256 sera examined In the sera from persons aged 71 or more there was an increase in number of positive titres (table I and fig 1) The total absence of positive sera in the age-group under 30 may be due to the relatively few sera available from this group There can be no doubt that the positive H I titres represent true antibody, as is shown by the results obtained with the M P test (tables II and III) Nor can it be assumed that recent infection with the Asiatic strain type of 1957 is concerned, because of the results with the C F test with soluble antigen of influenza virus A The first somewhat higher titre (87) was found in a person aged 71, and the first high titre (140) in a person aged 73 The youngest person with H I antibody was aged 39 (titre 54) The greatest incidence of positive titres was in persons aged 81 (8 of the 21 sera of this group showed inhibition)

Comparative titration of 49 positive sera against the Asiatic strain A/Japan/305/57, the strain A/Swine/15 and the mouse-adapted lines of 8 human A-strains from the period 1933–56 showed that in 17 sera (35%) the titre to the Asistic strain was higher than to any of the former strains (corresponding ages 76–94) In 2 sera a titre was present only to the Asiatic strain (corresponding ages 79–86) In 8 other sera the titre to the Asiatic strain was either about as high as the titre to one or more of the former strains, or amounted at least to 50% of the highest titre to one of these strains (corresponding ages 77–84) This finding is important, because it proves that in the ages 76–94 the Asiatic titres cannot in general be considered as having been caused by possibly existing shared minor antigen with known former strain types (see later) Meanwhile Davoli and Corsi (1957) have found pre-epidemic antibody to the Asiatic strain in Italian people, predominantly in the age-group 78–85

Antibody against Current Asiatic Strain Appearing after Vaccination with Monovalent Vaccines from Former Human A Strains

We had at our disposal 323 sera from people of different ages who had been vaccinated in 1956 and in the beginning of 1957 with monovalent vaccines of mouse-lines of former human A strains A/PR$_8$ (1934 U S A), A/FM$_1$ (1947 U S A), A/1951/Scandiv (1951 Ned), and A/1953 (1953 Ned)* Testing pre- and post-vaccination sera against the strain A/Asia/Japan/305/57 we found that a surprising number (9%) of the post-vaccination sera showed H I antibody against the Asiatic strain, even in the younger age-groups (table IV) These titres were again checked in duplicate on the same day A few M P tests done with pre- and post-vaccination sera again showed increases of true antibody against the current Asiatic strain in the post-vaccination samples The number of cases is too small to be analysed statistically in the different groups of people who received the different vaccines, but in every group increases of titre were found

Discussion

An outstanding finding is that the pattern of pre-epidemic Asiatic-influenza antibody in human sera shows a concentration in number and a rise in titre in people aged 71–94 Although the available number of sera in the age-group 0–30 was relatively small, it is very unlikely that, in this age-group, a similar antibody pattern would have been found as in the age-group 71 or more This phenomenon can therefore be compared with that demonstrated by Davenport et al (1953, 1955) and Hennessy et al (1955) of the appearance of high-titred H I antibody in people aged 35–38 (in 1953) against the dominant antigen of the influenza-A strain isolated from North American swine by Shope Fig 2 illustrates our confirmation of this work from a few sera investigated in the Netherlands

TABLE IV—POST-VACCINATION TITRES AGAINST INFLUENZA STRAIN A/ASIA/JAPAN/305/57 AFTER VACCINATION WITH FORMER HUMAN A STRAINS IN DIFFERENT AGE-GROUPS (MONOVALENT VACCINES)

Age-group (yr)	No vaccinated	No of positive H I titres	Height of post-vaccination H I titres[1]

* Mouse-protection test positive

° Mouse-protection test doubtful

The first conclusion that can be drawn from fig 1 is that the human race most probably has been in contact with the dominant hæmagglutinating antigen of the current Asiatic strain in the last quarter of the 19th century, and that the 1957 pandemic of Asiatic influenza represented, in all probability, a repetition of an epidemic from that period

The analysis of antibody in human sera of different age-groups against the dominant antigen of the influenza-A swine strain indicates that the pandemic of 1918–19 was most probably the origin of the swine antibody in man, and that this pandemic was caused by the swine-influenza virus (Laidlaw 1935, Shope 1936, Davenport et al 1953) It remains, however, much less certain when the Asiatic-influenza antibody pattern shown in fig 1 originated, because most probably this figure shows only a poor remnant of a pattern which was much more extensive in number of positive titres and in height of titres shortly after the epidemic from which it was derived

There are some indications that the antibody pattern shown in fig 1 originated in the classic pandemic of 1889–90 The first high titres (140 and 258) against the current Asiatic antigen appear in the pattern in the ages 73 and 76, pointing to a possible origin about 1881–84 The greatest concentration of positive sera starts from the age of 76, again pointing to a possible origin around 1881 No important epidemic of influenza was registered in Europe between 1875 and 1889 Most workers (e g , Ripperger 1892, Leichtenstern 1896), with the exception of Hirsch (1881), do not consider the epidemic of 1875 to be a true pandemic, and most probably it did not originate in central Asia

If we assume that the pattern shown in fig 1 originated in the pandemic of 1889–90, an explanation should be sought for the fact that, in the age-group 70–76, only 5 positive H I titres were found in 161 examined sera (3 1%) A

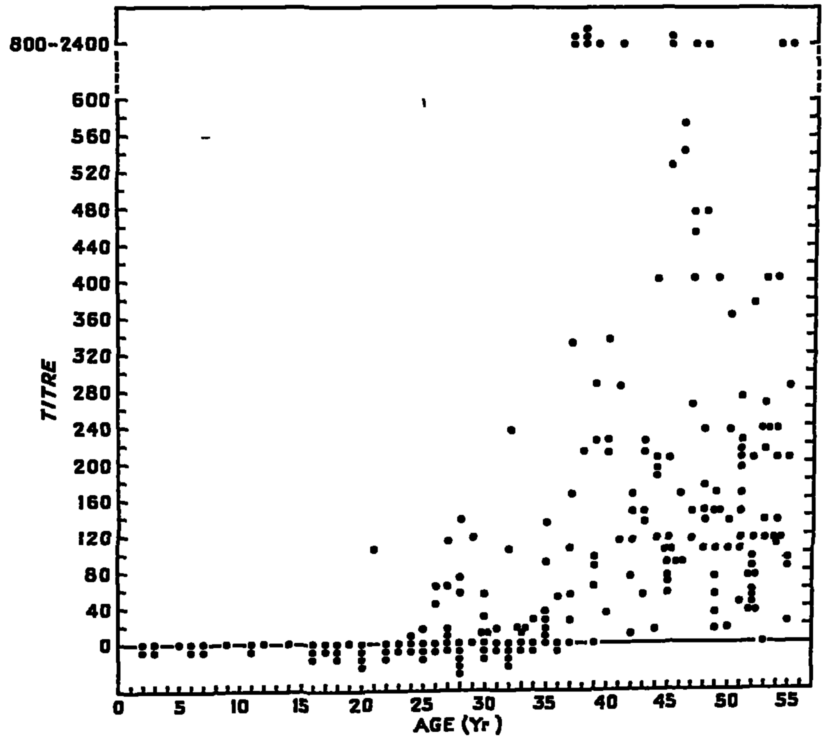

Fig 2—Age-distribution and H I antibody titres against influenza strain A/Swine/15 found in sera collected in Holland at beginning of 1957 (titres of <9 placed on or below zero line)

possible explanation may be that in the pandemic of 1889–90 school-children perhaps had a higher incidence of disease than had younger children, as was reported by several workers at that time (*Mitteilungen des Statistischen Amtes der Stadt München* 1891, Schmid 1895). Possibly other laboratories may supply more evidence of the presence of antibody in the age-group 70–76, because we must look on the pattern shown in fig. 1 as due largely to chance. The absence of a clear antibody pattern before the age of 70 is discussed below.

---

* These vaccines were kindly produced at our request by the Biological Laboratories of N V Philips Roxane, Weesp

The 1890 origin of the antibody pattern shown in fig. 1 can also be explained on theoretical grounds. It is almost certain that the pandemic of influenza of 1889–90 originated in central Asia. The first cases were described by Heyfelder (1889) in May, 1889, in Bokhara, and the Russian doctors at that time called the disease "Chinese" influenza. Although Cantlie (1891) described an epidemic of febrile respiratory disease in September, 1888, in Hong Kong, thought by him to have been influenza, we cannot accept this diagnosis, because of the high incidence of skin rash in these patients and the appearance of jaundice in several cases.

The epidemiology of "true" pandemics of influenza differs sharply from that of the waves of seasonal influenza. True pandemics start in a certain part of the world, spread with the speed of human traffic irrespective of climatic and seasonal influences, and show a high morbidity, especially in people aged less than 40, and a relatively low mortality in their "first" wave.

Since the discovery of the human influenza virus (Smith et al. 1933) we know that interpandemic (seasonal) influenza virus A is continuously circulating in the world population, changing from time to time its antigenic make-up, probably selected by the antibodies built up against the dominant antigens of previous strains, and that, after a new dominant antigen is acquired, the precursor strain disappears rapidly.

In this respect it is most important to consider the fact that, from the work of Davenport et al. (1953) and from fig. 2, it can be concluded that, after 1918, the human race was in contact with the swine antigen for another 7–13 years. Since, in the cross-H.I. test, antigenic overlapping between the swine strain and the first isolated human influenza strain A/WS (1933 England) is clearly present, it is conceivable that, after 1918, derivatives of the swine strain were circulating, most probably with a different dominant antigen but with an antigenic relationship to swine. Strain analysis after 1933 has further shown that all the main human-strain types which appeared in 1934–56 were probably derived subsequently from a precursor. How far the dominant swine antigen can be "followed" in the strains appearing after 1933 has not yet been investigated carefully enough, and further experiments in this respect should be made in the future. Summarising, we can assume that, so far as the influenza-A group is concerned, the period 1918–56 may be considered as the "swine-influenza" era, even if the dominant swine antigen has vanished for the most part in the isolates found after 1933.

It is not improbable that we may accept the same course of events for the hypothetical influenza-virus of 1889, and that 1889–1918 represents an "Asiatic-influenza" era. Since hypothetical influenza-A strains circulating shortly before 1889 did not represent a "true" pandemic type, it is less probable that the 1957 Asiatic strain should be identical with such a strain, by chance starting a pandemic again in Asia, than to assume that a carriership of a particular A strain in Asia exists, presumably in an animal, causing human pandemics at long intervals of time. In this respect it is worth while to notice also that the "true" pandemics of 1830 and 1782 are considered to have originated in China (Ripperger 1892), and that strains of influenza virus isolated from North American swine in 1930–54 do not show great changes in antigenic composition (Gompels 1953, Jensen and Peterson 1957).

If fig. 1 represents a remnant of the antibody pattern originating in 1889–90, there is no definite evidence of the persistence of the "old" Asiatic antigen for a short period after 1890. It should be emphasised, however, that, if it had been present after 1890, the height of the titres would have been considerably lower than that of those originating in the pandemic itself (compare fig. 2), and that most probably the antibody would have vanished almost completely.

The hypothesis that the Asiatic strain of 1957, or a precursor strain with some antigenic relationship, has been in circulation for a long time, causing only scattered cases of influenza, seems improbable, because it would be very difficult to explain why such a strain should start a true pandemic again in Asia. The same can be argued against the theory that the Asiatic strain has been derived from recent human A strains by mutation.

For all those reasons we believe that the antibody pattern shown in fig. 1 may well have originated in the pandemic of influenza in 1889–90, and that the pandemic of Asiatic influenza in 1957 may have been a repetition of it, emerging from a pre-existing carriership in central Asia.

In the future it may be of importance to test again the present collection of old-age sera against new strains of influenza virus A which may turn up. If by chance the theoretical mutant of the current Asiatic virus which may appear in future should be found to be inhibited by human sera of a younger age-group than 70–100 (in 1957), almost certain proof of the identity of the current strain with that of 1889 could be obtained. At the same time it could be shown that the direction of the possibly developing mutation of the current Asiatic strain was the same as the one manifesting itself after 1890.

Difficult to explain are the facts in table IV. If the post-vaccination increases in H.I. titre against the Asiatic antigen were confined to the age-group 40 or more, they might indicate a stimulation of antibody against a remnant of the Asiatic dominant antigen present in derivative strains of the Asiatic type, which perhaps turned up in 1890–1918, after which the swine strain started to become dominant. This phenomenon is actually seen when people aged less than 20 are vaccinated with the strain A/PR$_8$ (1934 U.S.A.). In some cases post-vaccination titres against the swine strain appear, which can be explained by assuming a small antigenic overlapping of this strain with the PR$_8$ strain (Davenport and Hennessy 1956, Jensen and Peterson 1957, and our own unpublished observations). Since, however, the H.I. antibody against the Asiatic antigen after vaccination with heterologous recent human A strains appears also in persons born long after 1918, this theory cannot completely explain the phenomenon.

A possible explanation could be that there is still a minor overlapping in hæmagglutinating antigen between the Asiatic strain and recent A strains, which cannot be demonstrated with the routine animal antisera and methods used in the cross-H I test but may be shown by a highly sensitive antibody response of some people The possibility that a minor hæmagglutinating Asiatic antigen may be situated within the virus particle of previous A strains should also be kept in mind Meyer et al (1957) came to the same preliminary conclusion when they observed occasional small increases of titre against strains of the Asiatic type in their tests with paired sera from epidemics of previous years in military personnel as well as a few low H I titres against the same strains in sera from recruits vaccinated with a mixture of former A strains The occasional low H I titres found by us in persons aged less than 70 may be explained in the same way, although no-one was found associated with a positive C F test with soluble antigen or with a previous vaccination This observation emphasises the need for new experiments in which careful attention should be paid to minor overlapping titres between former A strains (including the swine strain) and the Asiatic type The use of high-titred animal antisera produced with adjuvant vaccines might perhaps be helpful in these tests

Summary

Pre-epidemic antibody against the 1957 Asiatic influenza virus was found in greatest number and with highest titre in people aged 71 or more living in the Netherlands

This suggests that the 1957 pandemic of influenza was a repetition of an epidemic which appeared in the last quarter of the 19th century, and that this epidemic might well have been the pandemic of 1889–90, which also originated in Asia

Similar investigation in the future of a possible mutant of the current Asiatic virus might be of importance to substantiate this theory

Low increases of antibody titre against the current Asiatic strains were observed in some people in younger and older age-groups after vaccination with monovalent vaccines from former human A strains

To explain this phenomenon a careful study of eventually existing minor overlapping of hæmagglutinating antigen between the Asiatic strain, former human A strains, and the strain of swine influenza may be helpful

This investigation was made possible by a grant from the Board of Curators of the University of Leyden and by financial aid from the Institute of Preventive Medicine, Leyden We are indebted to Dr J H Bekker, Dr P S Blom, Dr G Blomhert, Prof J G G Borst, Prof F S P van Buchem, Prof P Formijne, Prof L A Hulst, Prof F L J Jordan, and Prof C L H Majoor for contributing sera, and Dr W J Bruins Slot and Dr S Braadbaart for enabling us to collect sera from hundreds of older people in the Municipal Old Folks Home at Rotterdam

WHEN the virus of Asian influenza was isolated in Singapore in May, 1957, it was found to be an influenza-A strain because it contained the soluble complement-fixing antigen common to all influenza-A strains It differed from all previous influenza-A strains, however, in that the hæmagglutination-inhibition test, which detects strain-specific antigens, showed no cross-reactions with any previous strain (Jensen 1957, Meyer et al 1957) This explains the finding that only a very small proportion of people before exposure to the virus had hæmagglutination-inhibiting antibodies against the Asian strain (Meyer et al 1957, Davoli and Corsi 1957, J Mulder, personal communication)

This absence of antibodies in the pre-epidemic sera gave a wonderful opportunity for studying the effect of the epidemic of Asian influenza on the serological status of the population It was first necessary to establish the effect of clinical illness due to the virus on the antibodies demonstrated by the hæmagglutination test This was done by testing pairs of sera from some patients in various school and other epidemics and from others admitted to hospital with pneumonia and other complications of influenza A group of university students were also bled five weeks after the epidemic, and the findings were compared with the histories in these persons of illnesses resembling influenza

Population studies were made by hæmagglutination tests on random sera collected before the outbreak between 1955 and 1957, some of which were pooled by age-group, and on individual and other pooled sera collected in November, 1957, two months after the peak of the epidemic Sera from patients with influenza in 1949, 1951, and 1956 and from persons inoculated with various influenza-virus vaccines in 1955 and 1956 were also tested by the same methods in the hope of throwing light on the relationship between the Asian-virus antigen and those appropriate to earlier influenza-A viruses

Materials and Methods

Sera were kept at –26°C for periods of a few weeks to 2 years, except for those collected in 1949 and 1951, which were freeze-dried.

Viruses—The strains of influenza virus used were FM1 1947, A/England/1/51, A/England/211/56 (all representative of past A strains and referred to later as A prime strains), and A/Singapore/1/57 Pools of virus for hæmagglutination-inhibition tests were made by intra-allantoic inoculation of 10-day embryonated eggs with a dilute suspension of virus After 48 hours' incubation at 35°C the allantoic fluids were harvested, pooled, and stored at –26°C in small bottles

Hæmagglutination-inhibition (H I) *tests* were made by a modification of the World Health Organisation's (1953) plastic-plate technique

---

*In receipt of a grant from the Medical Research Council

Phosphate-buffered saline solution (pH 7 2) was used instead of physiological saline solution and all the sera were treated overnight with cholera filtrate The method of preparing the cholera filtrate and that of treating the sera were as described by Hilleman and Werner (1953) This treatment was necessary because influenza A/Singapore/57 is very susceptible to non-specific inhibitor In all the experiments, except those on pooled sera and vaccination sera, red cells were obtained from the same fowl The titre of a serum was expressed as the reciprocal of the initial dilution producing partial inhibition

Complement-fixation tests —A modification of the method of Fulton and Dumbell (1949) was used, influenza-A soluble antigen being prepared from the chorio-allantoic membrane of eggs infected with the WS strain The methods used have been described previously (Balducci et al 1956)

Results

Serological Tests on Pairs of Sera from Patients with Influenza in the 1957 Epidemic

Both H I tests against A/Singapore/57 and complement-fixation tests using an influenza-A soluble antigen were done on 80 pairs of sera from patients with influenza They included sera from patients in two public schools, an R A F station, the university health service, and employees at a steel works The remainder (31) were from patients with influenza admitted to hospital mainly with complications—e g, pneumonia

Influenza-A virus of Asian type was isolated in eggs from three of these patients and from four of their contacts

Table I shows the results of the H I tests on these sera It will be seen that most of the acute specimens of serum from uncomplicated cases of influenza contained no detectable hæmagglutination-inhibiting antibody The acute specimen of serum was often collected rather late in the illness from the patients admitted to hospital, and antibody was detected in two-thirds of these sera

TABLE I—HÆMAGGLUTINATION-INHIBITION TITRES OF PAIRS OF SERA FROM CLINICAL CASES OF INFLUENZA

Category	Phase of illness	No of sera	Distribution of H I titres							Cases with rises of antibody
			< 10	10–15	20–30	40–60	80–120	160–240	> 240	
Uncomplicated influenza	Acute	49	46	3						27 (55%)
	Convalescent	49	19	9	6	7	7		1	
Admitted to hospital	Acute	31	10	5	8	4	2	1	1	21 (68%)
	Convalescent	31	5	1	5	1	4	5	10	

The convalescent sera contained antibody in 30 of the uncomplicated cases (61%) and in 26 (84%) of the hospital patients Fourfold or greater increases of antibody were detected by the H I test in 27 (55%) of uncomplicated cases and in 21 (68%) of the hospital patients

The results of the complement-fixation tests were similar Most of the acute specimens of serum gave titres of less than 4 Complement-fixing antibody was present in the convalescent serum of 84% of uncomplicated cases and 74% of the hospital patients Fourfold or greater increases of antibody were detected by the complement-fixation test in 36 (74%) of uncomplicated cases and in 18 (58%) of the hospital patients Thus in the uncomplicated cases the complement-fixation test was positive more often than the H I test.

13% of the patients showed no significant level of antibody in the convalescent serum by either test, a further 7% developed antibody detected only by the H I test, and 19% showed complement-fixing antibody only

From these results it is possible to guess that about 30% of the population of Sheffield who had attacks regarded as clinical influenza had no antibody detected by the H I test in their sera during convalescence

TABLE II—HÆMAGGLUTINATION-INHIBITION TESTS ON SERA FROM MEDICAL STUDENTS

History of clinical influenza	No positive	No negative	Total
Yes	17	3	20
Doubtful	2	1	3
No	5	19	24
Total	24	23	47

Sera with titres of 10 or more were considered positive.

Relationship between Positive Hæmagglutination-inhibition Test and History of Clinical Influenza

In the third week of November, 1957, five weeks after the peak of the outbreak in the university students, single samples of serum were collected from 47 first-year students At the same time they were asked whether or not they had had illnesses resembling clinical influenza The results of H I tests against A/Singapore/57 on these sera are shown in table II There was good correlation between a history of influenza and a positive H I test

The results showed that 5 (about 20%) of infections producing hæmagglutination-inhibiting antibody were subclinical Probably at least the same proportion of all infections, both with and without detectable serological response, were subclinical The results cited above showed that about 30% of all patients with presumed influenza had no detectable hæmagglutination-inhibiting antibody in their convalescent sera The figures for the above-mentioned students (4 of 23) are comparable with these Thus the H I test done on a single specimen of serum would detect only 70% of recent cases of clinical influenza but would reveal a further 20% with subclinical infections

Comparison of Antibodies in Population before and after the Asian Influenza Epidemic

Tests were done to study the effect of the 1957 epidemic on hæmagglutination-inhibiting antibodies to Asian virus in the population of Sheffield and neighbourhood It was hoped that information would be obtained about the extent of infection in the population during the epidemic

Pre-epidemic sera —Table III shows the results of the H I tests against A/Singapore/57 on 154 sera collected in England before July, 1957 Most of these sera had come from the north of England from suspected cases of toxoplasmosis, 39 were from suspected cases of virus infection from Sheffield, and 19 were from persons aged 80 or more in an old people's home

TABLE III—RESULTS OF HÆMAGGLUTINATION-INHIBITION TESTS AGAINST A/SINGAPORE/57 ON SERA COLLECTED BEFORE THE EPIDEMIC

Age (yr)	No tested	No with titres of 10 or more	Titres
0–9	23	1	80
10–19	21	0	
20–29	28	1	20
30–39	27	2	10 & 30
40–49	10	0	
50–59	13	0	
60–69	11	1	30
70–79	2	0

90–92	1	0	
Total	154	6	

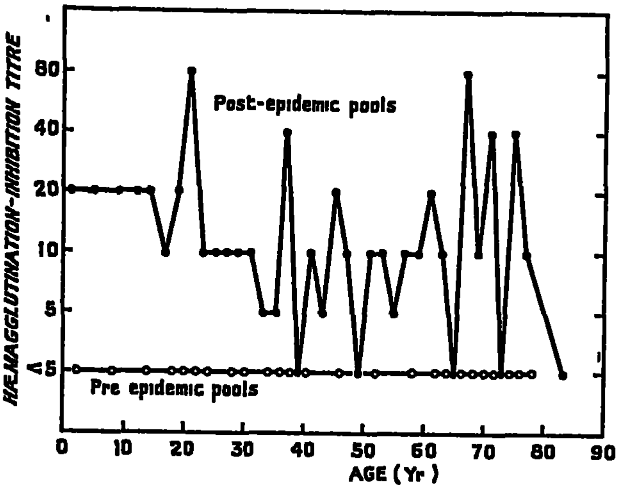

Fig. 1—Titres of pools of sera tested against A/Singapore/57.

6 of the sera gave titres of 10 or more. They were from persons of various ages, and only one of these belonged to the old-age group. In repeat experiments the numbers of such sera varied with the batch of cholera filtrate used, and in one experiment, in which a particularly weak batch was used, 25 sera gave positive results. Neutralisation tests were not done, so it was impossible to decide whether the six sera actually contained antibody against the Asian strain or whether the result was due to non-specific inhibitor. In addition to these, none of the sera taken from the 168 persons before vaccination in 1955 and 1956 (see below) contained inhibitor against the Asian strain. These people were mostly young adults.

Besides these individual sera, pools of sera collected in 1955 were tested by hæmagglutination-inhibition against A/Singapore/57. The sera had been pooled according to age in two-year age-groups, up to 50 sera being put into each pool. 25 of the pools between the age of 2 and 78 were tested (fig. 1), and all had titres of less than 5. This was very different from the results obtained with similar serum pools collected in 1954 in Sheffield and tested against other viruses (Davenport et al. 1955). It thus appears that most of the sera from the population of Sheffield were devoid of detectable antibody against the Asian strain before the outbreak.

Post-epidemic sera.—The peak of the epidemic in Sheffield was during the week ending Sept. 21, 1957. Between Nov. 1 and Nov. 30, 1957, 1660 sera were collected by the Sheffield Blood Transfusion Service, the Sheffield Public Health Laboratory, and the pathological laboratories of many of the Sheffield hospitals. Most of them came from blood-donors or were sent for Wassermann tests, the rest being sent to the laboratories for various routine tests. All these sera were tested after pooling according to age, and many were also tested individually.

637 sera were tested individually against the A/Singapore/57 virus (fig. 2). 283 (44%) had titres of 10 or more. The percentage of sera positive in each 10-year age-group was 16–71%, being highest under the age of 20 and lowest between the ages of 60 and 69. This variation may reflect the attack-rate in the different age-groups but may also have been partly due to the fact that different pools of antigen were used in the various tests.

All the 1660 sera (including those tested individually) were pooled according to age as follows: (1) between the ages of 17 and 76 they were pooled in 2-year age-groups, (2) the age ranges of the remaining pools were 0–3, 4–7, 8–11, 12–13, 14–16, 77–79, and 80–88, and (3) each pool consisted of 50 sera, except those from persons aged less than 16 and persons aged more than 66, which contained 21–47 sera.

All the pools were tested by hæmagglutination-inhibition against A/Singapore/57 at the same time that the 1955 pools were tested. Thus in one experiment, using the same antigen, red cells, and cholera filtrate, the age-distribution of antibody against the Asian virus was determined in 1660 post-epidemic sera. The results are shown in fig. 1. There was considerable variation from pool to pool, and there was no obvious trend with age. But there was a remarkable difference in the results of the tests against A/Singapore/57 virus with the sera collected before and after the epidemic.

Cross-hæmagglutination-inhibition Tests

With sera from cases of influenza.—Table IV shows the results of tests on acute and convalescent specimens of serum from patients with influenza in 1949, 1951, 1956, and 1957. None of the sera collected before 1957 showed rises in inhibition titre against A/Singapore/57, although

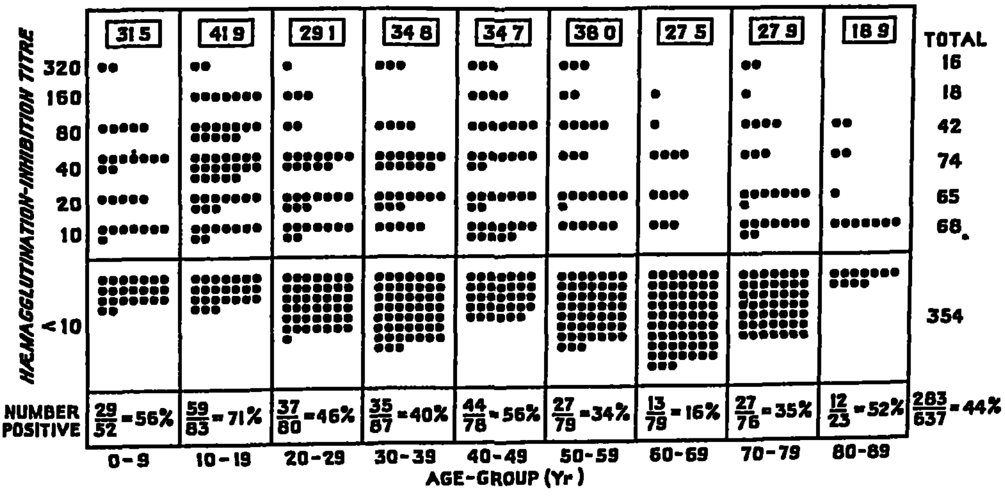

Fig. 2—Post-epidemic sera tested against A/Singapore/57. Numerals in rectangles denote geometric means of sera with titres of 10 or more.

11	0/48		60/60	120/120	0/120

0 less than 4 in the complement-fixation tests and less than 5 in the hæmagglutination-inhibition tests

all showed rises in titre against the strains prevalent at the time of collection. Most of them were from young adults 11 pairs of sera from patients with influenza in the 1957 epidemic which showed rises in titre against A/Singapore/57 were tested against A/England/51 and A/England/56 Whereas some of these sera contained antibody against these "A prime" strains, in only 2 cases was there a rise in titre. This shows that anamnestic reactions, such as occur between influenza-"A prime" and influenza-A strains (Stuart-Harris and Miller 1947), can also occur between the Asian virus and "A prime" strains

With sera from vaccinated persons—H I tests against A/Singapore/57 were done on 168 pairs of sera from people vaccinated with one dose of influenza vaccine in 1955 and 1956 The first specimen was taken before vaccination and the second about four weeks after For those given oil adjuvant vaccines a third specimen was taken three months after vaccination. 32 persons were given a monovalent vaccine containing A/England/54, 15 a monovalent vaccine containing A/Malaya/54, 14 a monovalent vaccine containing A/England/55, 42 a monovalent oil adjuvant vaccine containing A/England/56, and 65 a polyvalent vaccine containing swine, PR8, and FM1 influenza-A viruses Most of the subjects were aged 18–25, but 7 given the polyvalent vaccine, 7 given the A/England/54 vaccine, and an unknown number given the A/England/56 vaccine were aged more than 25 Most of the 168 sets of sera had shown rises in titre by the H I test against the homologous antigen

The H I titres of pre- and post-vaccination specimens from 160 of the vaccinated persons were less than 10 In the remaining 8 sets of sera (5%) the titres of the first specimen were less than 10 and those of the second or third were 15 (4 instances), 20, 30, and 40 (2 instances) 4 of these titres were confirmed on repetition 2 of the sera were from persons given the polyvalent vaccine and 6 the A/England/56 monovalent vaccine.

It thus appears that inhibitor against the Asian-virus antigen was occasionally stimulated to appear in the serum after immunisation with a single injection of vaccine made from an influenza virus recovered before 1957 Our inability to detect similar appearances of inhibitor after infection with the latter viruses may have been due to the small number of available sera tested Meyer et al (1957) detected inhibitor to the Asian virus in sera from some patients with clinical influenza before the Asian epidemic. Such naturally developing antibody would explain our own finding of occasional inhibitor to the Asian virus antigen in the pre-epidemic sera

Discussion

The serological results obtained in Sheffield in cases of Asian influenza are similar to those found during previous epidemics of influenza A and are in conformity with the results of other workers The H I test using the Singapore virus showed a rise of antibody in 60% and the complement-fixation test in 68% of cases The corresponding results obtained during the 1951 epidemic were that H I tests with the appropriate virus antigen were positive in 59% and complement-fixation tests using soluble antigen were positive in 75% of cases (Stuart-Harris 1953) During the Asian epidemic the H I test detected antibody in convalescence in 70% of clinical illnesses but also indicated subclinical infection in 20% of the population Lim et al (1957) found in Singapore that the H.I test detected antibody in 67% of patients with Asian influenza admitted to hospital and revealed subclinical infection in 13% of persons who remained symptom-free

The study of the distribution in the population of Sheffield of antibody detected by the H I test after the epidemic showed that at least 16–71% of persons of various ages had become infected Even 30–50% of those aged 70 or more showed evidence of infection The appearance of antibody in a high proportion of young adults and children agreed well with the numbers of illnesses observed by practitioners However, many doctors in Sheffield commented that there were relatively fewer illnesses in those aged more than 40, and the attack-rate in Beckenham measured by Fry (1958) fell progressively after the age of 20 It seems likely that many infections in the older persons in Sheffield were either very mild or asymptomatic. The average attack-rate in the population which could be surmised from these serological results was at least 50%

The geometric mean titres of antibodies found at various ages in the post-epidemic period, if we ignore the sera which did not inhibit agglutination at 1 in 10 dilution, showed relatively little variation with age (fig 1) The highest mean titre was in the second decade, and that in persons aged more than 60 was not so high This appeared to indicate a relatively uniform serological response to infection such as would be expected if the Asian-virus antigen had not been experienced previously by those who became ill

The finding of inhibitor to the Asian virus in 6 of 322 sera collected before the epidemic has to be considered in association with the observed appearance of inhibitor in 8 of 168 persons immunised with various influenza-virus vaccines which did not contain Asian virus We have no proof that the inhibitor was neutralising antibody, but the assumption that this was so is reasonable. These instances of serum inhibition were infrequent and bore no apparent relation to age. Mulder (1957) has brought forward evidence that antibody to the Asian virus was

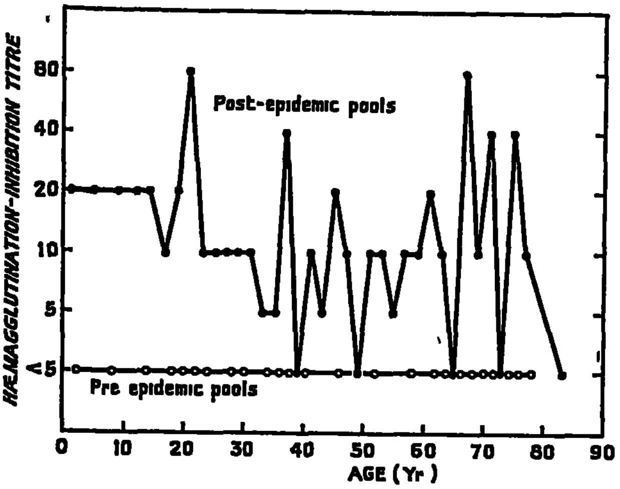

Fig 1—Titres of pools of sera tested against A/Singapore/57

6 of the sera gave titres of 10 or more They were from persons of various ages, and only one of these belonged to the old-age group In repeat experiments the numbers of such sera varied with the batch of cholera filtrate used, and in one experiment, in which a particularly weak batch was used, 25 sera gave positive results Neutralisation tests were not done, so it was impossible to decide whether the six sera actually contained antibody against the Asian strain or whether the result was due to non-specific inhibitor In addition to these, none of the sera taken from the 168 persons before vaccination in 1955 and 1956 (see below) contained inhibitor against the Asian strain These people were mostly young adults

Besides these individual sera, pools of sera collected in 1955 were tested by hæmagglutination-inhibition against A/Singapore/57 The sera had been pooled according to age in two-year age-groups, up to 50 sera being put into each pool 25 of the pools between the age of 2 and 78 were tested (fig 1), and all had titres of less than 5 This was very different from the results obtained with similar serum pools collected in 1954 in Sheffield and tested against other viruses (Davenport et al 1955) It thus appears that most of the sera from the population of Sheffield were devoid of detectable antibody against the Asian strain before the outbreak

Post-epidemic sera—The peak of the epidemic in Sheffield was during the week ending Sept 21, 1957 Between Nov 1 and Nov 30, 1957, 1660 sera were collected by the Sheffield Blood Transfusion Service, the Sheffield Public Health Laboratory, and the pathological laboratories of many of the Sheffield hospitals Most of them came from blood-donors or were sent for Wassermann tests, the rest being sent to the laboratories for various routine tests All these sera were tested after pooling according to age, and many were also tested individually

637 sera were tested individually against the A/Singapore/57 virus (fig 2) 283 (44%) had titres of 10 or more The percentage of sera positive in each 10-year age-group was 16–71%, being highest under the age of 20 and lowest between the ages of 60 and 69 This variation may reflect the attack-rate in the different age-groups but may also have been partly due to the fact that different pools of antigen were used in the various tests

All the 1660 sera (including those tested individually) were pooled according to age as follows (1) between the ages of 17 and 76 they were pooled in 2-year age-groups, (2) the age ranges of the remaining pools were 0–3, 4–7, 8–11, 12–13, 14–16, 77–79, and 80–88, and (3) each pool consisted of 50 sera, except those from persons aged less than 16 and persons aged more than 66, which contained 21–47 sera

All the pools were tested by hæmagglutination inhibition against A/Singapore/57 at the same time that the 1955 pools were tested Thus in one experiment, using the same antigen, red cells, and cholera filtrate, the age-distribution of antibody against the Asian virus was determined in 1660 post-epidemic sera The results are shown in fig 1 There was considerable variation from pool to pool, and there was no obvious trend with age But there was a remarkable difference in the results of the tests against A/Singapore/57 virus with the sera collected before and after the epidemic

Cross-hæmagglutination-inhibition Tests

With sera from cases of influenza—Table IV shows the results of tests on acute and convalescent specimens of serum from patients with influenza in 1949, 1951, 1956, and 1957 None of the sera collected before 1957 showed rises in inhibition titre against A/Singapore/57, although

0 less than 4 in the complement-fixation tests and less than 5 in the hæmagglutination-inhibition tests

all showed rises in titre against the strains prevalent at the time of collection Most of them were from young adults 11 pairs of sera from patients with influenza in the 1957 epidemic which showed rises in titre against A/Singapore/57 were tested against A/England/51 and A/England/56 Whereas some of these sera contained antibody against these " A prime " strains, in only 2 cases was there a rise in titre This shows that anamnestic reactions, such as occur between influenza-" A prime " and influenza-A strains (Stuart-Harris and Miller 1947), can also occur between the Asian virus and " A prime " strains

With sera from vaccinated persons—H I tests against A/Singapore/57 were done on 168 pairs of sera from people vaccinated with one dose of influenza vaccine in 1955 and 1956 The first specimen was taken before vaccination and the second about four weeks after For those given oil adjuvant vaccines a third specimen was taken three months after vaccination 32 persons were given a monovalent vaccine containing A/England/54, 15 a monovalent vaccine containing A/Malaya/54, 14 a monovalent vaccine containing A/England/55, 42 a monovalent oil adjuvant vaccine containing A/England/56, and 65 a polyvalent vaccine containing swine, PR8, and FMI influenza-A viruses Most of the subjects were aged 18–25, but 7 given the polyvalent vaccine, 7 given the A/England/54 vaccine, and an unknown number given the A/England/56 vaccine were aged more than 25 Most of the 168 sets of sera had shown rises in titre by the H I test against the homologous antigen

The H I titres of pre- and post-vaccination specimens from 160 of the vaccinated persons were less than 10 In the remaining 8 sets of sera (5%) the titres of the first specimen were less than 10 and those of the second or third were 15 (4 instances), 20, 30, and 40 (2 instances) 4 of these titres were confirmed on repetition 2 of the sera were from persons given the polyvalent vaccine and 6 the A/England/56 monovalent vaccine

It thus appears that inhibitor against the Asian-virus antigen was occasionally stimulated to appear in the serum after immunisation with a single injection of vaccine made from an influenza virus recovered before 1957 Our inability to detect similar appearances of inhibitor after infection with the latter viruses may have been due to the small number of available sera tested Meyer et al (1957) detected inhibitor to the Asian virus in sera from some patients with clinical influenza before the Asian epidemic Such naturally developing antibody would explain our own finding of occasional inhibitor to the Asian virus antigen in the pre-epidemic sera

Discussion

The serological results obtained in Sheffield in cases of Asian influenza are similar to those found during previous epidemics of influenza A and are in conformity with the results of other workers The H I test using the Singapore virus showed a rise of antibody in 60% and the complement-fixation test in 68% of cases The corresponding results obtained during the 1951 epidemic were that H I tests with the appropriate virus antigen were positive in 59% and complement-fixation tests using soluble antigen were positive in 75% of cases (Stuart-Harris 1953) During the Asian epidemic the H I test detected antibody in convalescence in 70% of clinical illnesses but also indicated subclinical infection in 20% of the population Lim et al (1957) found in Singapore that the H I test detected antibody in 67% of patients with Asian influenza admitted to hospital and revealed subclinical infection in 13% of persons who remained symptom-free

The study of the distribution in the population of Sheffield of antibody detected by the H I test after the epidemic showed that at least 16–71% of persons of various ages had become infected Even 30–50% of those aged 70 or more showed evidence of infection The appearance of antibody in a high proportion of young adults and children agreed well with the numbers of illnesses observed by practitioners However, many doctors in Sheffield commented that there were relatively fewer illnesses in those aged more than 40, and the attack-rate in Beckenham measured by Fry (1958) fell progressively after the age of 20 It seems likely that many infections in the older persons in Sheffield were either very mild or asymptomatic The average attack-rate in the population which could be surmised from these serological results was at least 50%

The geometric mean titres of antibodies found at various ages in the post-epidemic period, if we ignore the sera which did not inhibit agglutination at 1 in 10 dilution, showed relatively little variation with age (fig 1) The highest mean titre was in the second decade, and that in persons aged more than 60 was not so high This appeared to indicate a relatively uniform serological response to infection such as would be expected if the Asian-virus antigen had not been experienced previously by those who became ill

The finding of inhibitor to the Asian virus in 6 of 322 sera collected before the epidemic has to be considered in association with the observed appearance of inhibitor in 8 of 168 persons immunised with various influenza-virus vaccines which did not contain Asian virus We have no proof that the inhibitor was neutralising antibody, but the assumption that this was so is reasonable These instances of serum inhibition were infrequent and bore no apparent relation to age Mulder (1957) has brought forward evidence that antibody to the Asian virus was present in Holland in some aged persons before the epidemic and was rare in persons aged less than 80 He also observed (personal communication) the development of antibody after immunisation with an influenza vaccine which did not contain the Asian strain Our own results do not entirely conform with Mulder's view that the Asian virus is essentially the virus responsible for the 1890 pandemic An alternative explanation is that the Asian virus shares a minor antigenic component with some of the influenza viruses experienced before 1957 This minor component might represent the survival of a major antigen from some virus causing a human pandemic in the past It could form the basis for a genetic variation in which the minor component had become the major antigen recognised in 1957 as that of the Asian virus

Summary

H I antibody to the Asian influenza-virus antigen was detected in 70% and complement-fixing antibody to the soluble A antigen in 80% of convalescent sera from 80 cases of influenza with or without complications in Sheffield during the 1957 epidemic of Asian influenza

In 47 students H I tests on sera taken after the epidemic showed that 20% of infections were asymptomatic

6 of 322 sera collected before the epidemic contained inhibitor to the Asian virus 283 (44%) of 637 sera collected after the epidemic in Sheffield contained inhibitor, the number varying between 16% and 71% in persons of different ages

Pools of sera collected before 1957 and assembled by age showed no H I antibody to the Asian virus Similar pools of sera collected after the epidemic showed antibody in amounts varying within wide limits Probably at least half the population had been infected during the epidemic

H I antibody against the Asian virus appeared in the serum of 8 of 168 persons vaccinated with " A prime " and polyvalent vaccines but was not detected in the convalescent sera from 11 patients with influenza before 1957

The significance of the results is discussed in regard to the relationship between the Asian and other influenza-A viruses

We wish to thank Dr D W S Sheldon, of Repton School, Dr E K Morris, of Sedbergh School, Dr J Gregory, of Hadfield's steel works, Dr H R Worth and Dr P W W Gifford, of the university health service, and Squadron-Leader A F Hignell, R A F, for their cooperation It is impossible to name individually all our colleagues in the clinical and pathological services of the hospitals in Sheffield who assisted in the collection of the large number of sera We are particularly grateful to all of these and to Dr C C Bowley, director of the Sheffield Blood Transfusion Laboratory, and Dr E H Gillespie, director of the Public Health Laboratory

STRAIN-SPECIFIC COMPLEMENT-FIXATION TEST IN ANTIGENIC ANALYSIS AND SERODIAGNOSIS OF INFLUENZA *

Werner Henle

From the Division of Virology, Department of Public Health and Preventive Medicine, School of Medicine, University of Pennsylvania and the Children's Hospital of Philadelphia, Pennsylvania

Difficulties have arisen in the use of the hæmagglutination-inhibition test for antigenic analyses of strains of influenza virus by specific immune sera and for strain-specific serodiagnosis

Uncertainty in the interpretation of the results has been introduced by (1) phase variations in the viruses, on adaptation to laboratory hosts, as regards the degree of agglutination or the species of red cells agglutinated, and (2) differential susceptibilities of strains to one or more of the non-specific inhibitors present in immune sera derived from different animals Though several techniques are used for removing inhibitors from sera, none is universally successful, and there is no assurance that specific antibody levels remain unaffected For these reasons other methods of determining antigenic patterns and strain-specific antibody responses were sought

The complement-fixation test (C F T) is highly satisfactory for these purposes so long as the type-specific soluble antigen (S) common to all strains of one type and the strain-specific virus antigen (V) are clearly separated Equally essential is the use of anti-S sera free from anti-V (for proving absence of S in V) and, conversely, of anti-V sera devoid of antibodies to S These requirements have not generally been met in the past, but these reagents can now be produced regularly The non-specific inhibitors of hæmagglutination do not interfere with the C F T

Methods

The *S-antigen* is obtained by exposing virus particles to ether (Hoyle 1952, Lief and Henle 1956a) The internal S thus released is freed from all V by exhaustive adsorption on to chicken and guineapig red cells

Anti-S sera are produced by intranasal inoculation of guineapigs with small doses of active virus, followed after five or more weeks (when initially formed anti-V has disappeared) by an intraperitoneal injection of S prepared from a distantly related homotypic strain Thus only anti-S is boostered (Lief et al 1958)

Virus particles separated from infected allantoic fluids by two cycles of adsorption on to and elution from red cells are suitable as *V antigens* for C F T , since such suspensions are usually free from external S (Lief and Henle 1956b)

Guineapig *anti-V sera* are produced by three or more intraperitoneal injections of the hæmagglutinin fraction (devoid of external and internal S) obtained from ether-treated elementary bodies by the red-cell adsorption-elution procedure (A Fabiyi, F S Lief, and W Henle, unpublished)

Results

Cross-matching of V antigens of 36 type-A strains, isolated between 1931 (swine influenza S-15 strain) and 1957 (A-Japan-305), with the corresponding anti-V sera in block titrations revealed antigenic patterns in general

agreement with those obtained in other laboratories by hæmagglutination-inhibition methods (Hirst 1952, Hilleman 1951, Jensen and Francis 1953) The anti-Asian V serum (A-Japan-305) reacted to some extent with WS (1933) V, and anti-V sera to a 1951 and 1953 strain fixed complement to low titres in the presence of Asian V Such " one-way cross-reactions ", seen also in other combinations and often extending over several type-A families of strains, may reflect differences in the in-vitro and in-vivo antigenicity of some components

The strain-specific anti-V sera were effective in the rapid identification of new isolates of virus during outbreaks of A¹ and Asian influenza in 1957 In most cases the identity and antigenic relationships were established with first chick embryo-passage materials, so long as the amniotic or the allantoic fluids contained more than 20 hæmagglutination units per ml (F S Lief, M Ostapiak, A Fabiyi, and W Henle unpublished) Rarely three chick embryo passages were required before these determinations were feasible.

The V antigens were found suitable for strain-specific serodiagnosis of influenza (F S Lief and W Henle, unpublished) More than 90% of more than 800 cases of Asian influenza revealed significant increases in antibodies to the specific V antigen An increase in type-specific anti-S was noted in all cases except those in very young children In most instances it preceded development of anti-Asian V because, most likely, it represented usually a recall Absence of anti-V responses was referable to premature collection of convalescent blood

The anti-V responses during the Asian influenza epidemic and the preceding A¹ outbreak were rarely restricted to the infecting viruses, if they were, it was mainly in very young patients The spectrum of these responses was by no means limited to strains circulating during the life-span of the individual Table I presents the serological data in a few selected cases None of the patients had anti-V to the infecting strains in the acute-phase sera, so long as the samples of sera were taken in the first few days of illness, but all the convalescent sera were positive Reactions with other V antigens in the acute-phase sera reflected to some extent the patient's age, in that positive results with early strains, such as S-15 and PR8, were noted mainly in older age-groups, but there were exceptions—e g , cases 1 and 4 Yet in the convalescent sera responses were observed in many cases to V-antigens prevalent before the patient's birth In a considerable number of the A¹ infections (about 35%) in addition antibodies developed to Asian V before this agent appeared These reactions showed no apparent relation to the patient's age Such responses were recorded previously in A¹ patients (Meyer et al 1957) and persons immunised with pre-Asian influenza vaccines (Mulder and Masurel 1958)

The results obtained with the acute-phase sera appear to be in agreement with those of previous antibody surveys using hæmagglutination-inhibition tests (Mulder and Masurel 1958, Davenport et al 1953, Hennessy et al 1955) in that, with increasing age, antibodies to progressively earlier strains were found This has been interpreted to mean that the virus responsible for the initial influenza in childhood determines the antibody responses to subsequent exposures to antigenically different strains and, with it, the antibody patterns found throughout life If this interpretation is correct, the results suggest that the pandemic of 1918–19 was caused by a strain of what is now known as swine influenza virus (Shope 1936), and that of 1888–89 by an agent closely related to Asian influenza virus (Mulder and Masurel 1958), but the fact that some relatively young patients responded with antibodies to the S-15, PR8, and Japan-305 strains cannot be overlooked The development of anti-V in a patient to strains to which he could not possibly have been previously exposed suggests other interpretations

A broadening of antibody responses in animals after

* Serum titre at time of exposure/titre 3–4 weeks later

repeated infections or intraperitoneal injections of active virus has been observed in early studies (see Van Rooyen and Rhodes 1948) This problem was reinvestigated by repeated intranasal inoculations of guineapigs at intervals of ten to twenty-one weeks with active influenza viruses of progressively later vintage or even with the same strain

The first exposure usually induced strain-specific anti-V responses—i e , to the homologous and closely related strains

On second and subsequent exposures these antibodies were recalled and, *in addition, whether the same or different viruses* were used for reinoculations, the antibody spectra rapidly broadened The examples offered in table II revealed that ultimately antibodies were formed to V antigens which were not detectably represented in the infecting strains, including Asian V

It was noted also that, after second or third exposures, the ensuing antibody levels declined at slower rates than after the first infection

The anti-V reactions observed at the time of the third or fourth exposures were not restricted to the viruses used for previous inoculations

Discussion

These results indicate that influenza strains contain a multiplicity of antigens The dominant, and possibly also the minor, directly detectable components determine the antibody responses on primary infection (Jensen and Francis 1953) Recall of these antibodies on subsequent exposures to different type-A viruses, as well as the anti-V responses to antigens not measurable in the infecting agents, suggests that most, if not all, of the various antigenic components are present mainly at submeasurable levels in any of the strains Because of the low concentration of most of the antigens several exposures are required before many of the antibodies appear in the serum

If these observations apply to man, the presence of *antibodies to a wide spectrum of* V *antigens may reflect* in part the multiplicity, and possibly spacing and severity, of previous exposures, and not only the antigenic structure of the virus responsible for the primary infection The older the person, the more influenza infections he is likely to have experienced in the past The presence of antibodies to swine or Asian influenza viruses in the older age-groups does not necessarily denote, therefore, that they had been infected with these specific agents at the time of the agents' prevalence Multiple infections with other strains at later dates also could have ultimately produced these antibodies This problem may be resolved in the future, depending on whether the age-distribution of antibodies to early strains will remain unchanged in ten or more years, or whether anti-S-15 or anti-PR8 reactions will be found gradually in higher age-groups

It remains to be shown that the various anti-V reactions recorded reflect immunity If so, present immunisation procedures for man deserve reconsideration It has been observed that guineapigs, after as many as six intraperitoneal injections of non-infectious hæmagglutinin fractions, still yield strain-specific sera, whereas, as shown above, a few intranasal instillations of active virus induce broad responses, covering antigens not only of past but also subsequent prevalence

Summary

A new technique is described for the antigenic analysis of influenza viruses and serological diagnosis of influenza The method, a strain-specific complement-fixation test with the V (or viral) antigen, avoids the problems of nonspecific inhibitors and antibody-virus avidity which make the interpretation of the hæmagglutination-inhibition test so difficult

By means of this technique it was possible to type Asian viruses rapidly and to achieve a positive serological diagnosis in more than 90% of 800 paired sera The antibody responses, however, were rarely restricted to the infecting strain, and were in many cases broad enough to cover strains prevalent before the birth of the patients

Experimentally, it was found that guineapigs infected repeatedly with the same strain or with strains of progressively later vintage gradually developed a broadening antibody response which embraced strains not included in the infecting strains—e g , the Asian strain

It is concluded that antibody to Asian virus does not necessarily denote infection with that particular strain at the time when this virus was prevalent but could be produced by multiple infection with other strains at later dates

SEROLOGICAL trials of an influenza vaccine prepared from the Asian strain before the epidemic, showed, in contrast to previous experience (Beveridge 1944), that two doses were needed for a good serological response (Medical Research Council 1958, Commission on Influenza 1957) A further trial was therefore arranged in November, after the epidemic, by the Directorate of Hygiene and Research of the Royal Air Force at the request of the Medical Research Council's Committee on Influenza and other Respiratory Virus Vaccines

The object of this trial was to determine the serological response to one and two inoculations of the above vaccine in volunteers who had been exposed, but *not ill*, and in those who had had influenza in the autumn epidemic

* Where result was quoted as being < 1/10, it was assumed to be ≤ 1/5

The vaccine was prepared from A/Singapore/1/57, containing about 7000 hæmagglutinating units per dose of 1 ml, by Dr F Himmelweit of the Wright-Fleming Institute

Material and Methods

Two Royal Air Force stations with different attack-rates during the epidemic were chosen for the trial Station A, which had a mild outbreak causing an admission-rate to sick quarters of 12%, provided 26 volunteers who had had no clinical respiratory illness during the epidemic Station B had a severe outbreak of influenza A (Asian) with an admission-rate to sick quarters of 40% 57 airmen from this station volunteered 33 of these had had a clinical illness resembling influenza during the epidemic, the rest had not been ill

All these volunteers received one dose of vaccine Half of each group, picked by use of a table of random numbers, received a second similar dose three weeks later Members of each group were bled (into evacuated 'Venules') before the first inoculation, and again at intervals of three and six weeks The serum was separated and stored at –20°C When all samples had been collected they were divided at random between the laboratories of Mill Hill and Sheffield, where the serological tests were made Those testing the sera did not know from which group the samples had been obtained. Antihæmagglutination tests were performed with the A/Singapore/1/57 virus and the sera treated with *Vibrio choleræ* extract, according to the recommendations of the W H O expert committee (World Health Organisation 1953)

There was no respiratory illness among the volunteers during the period of the trial It was found that of those with no clinical history of influenza during this epidemic only 24% had antibodies before inoculation, whereas 64% of those with a clinical history of influenza had antibodies before inoculation

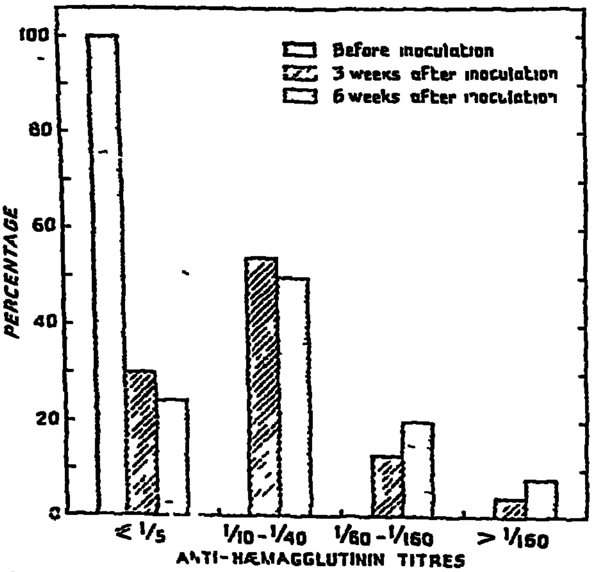

Fig 1—Distribution of titres 3 and 6 weeks after a single inoculation of vaccine in 27 individuals with initial antibody titres of ≤ 1/5

Results

The antihæmagglutination titres in the vaccinated individuals are summarised in the table and figs 1–4 The titres are shown in the figure as the percentages of individuals with titres within a given range, and figs 1–4 show antibody distributions in individuals with initial antibody titres of 1 in 5 or lower and in those with initial titres higher than 1 in 5, inoculated with one or with two doses of vaccine

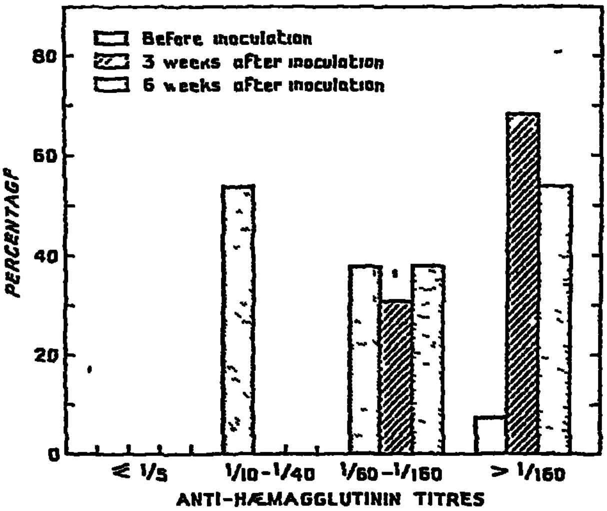

Fig 2—Distribution of titres 3 and 6 weeks after a single inoculation of vaccine in 14 individuals with an initial antibody titre of > 1/5

The table and fig 1 show that people with no initial antihæmagglutinin reacted poorly to a single dose of Asian vaccine. This finding agrees with the results of many other workers—e g, Commission on Influenza (1957), Medical Research Council Committee on Influenza and other Respiratory Virus Vaccines (1958)

On the other hand, a single inoculation of the same vaccine gave a much better response in individuals with initial titres of 1 in 5 or more (fig 2) due to virus-A infection—in most cases associated with a clinical attack of influenza in the epidemic This is also illustrated in the table, showing a higher geometric mean titre after inoculation This suggests that previous experience with this antigen had sensitised the antibody-producing mechanism, and in support of this the results in fig 3 and the table indicate that two inoculations of vaccine, given at an interval of three weeks to individuals without initial antibody, led to a good *secondary* response Comparison of figs 1 and 3 shows that the high titres after two inocula-

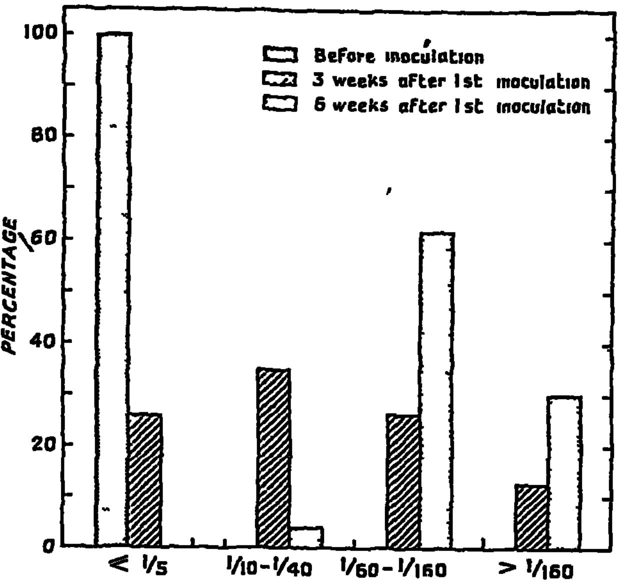

Fig 3—Distribution of titres 3 and 6 weeks after initial inoculation in 23 individuals with an initial antibody titre of < 1/5, given two doses of vaccine at 3-week intervals

tions cannot be due to a delayed response to the first inoculation

From fig 4 and the table it is clear that individuals with initial antibody titres of 1 in 5 or more received a booster effect from a single dose of vaccine but did not develop much higher titres from a second dose of vaccine Beveridge (1944) found that individuals vaccinated with REL and LEE strains of influenza virus A and B did not get a better response from two doses of vaccine given at an interval of two weeks than from a single dose The present results confirm his conclusion for viruses of which the inoculated individuals have had previous antigenic experience But with new influenzal antigens it appears that two antigenic stimuli are needed to produce a good antibody response

These results indicate the requirements for a good serological response, but they tell us nothing of the requirements for protection Unfortunately the clinical trials designed to compare one dose with two doses of Asian vaccine could not be carried out because the epidemic came too early

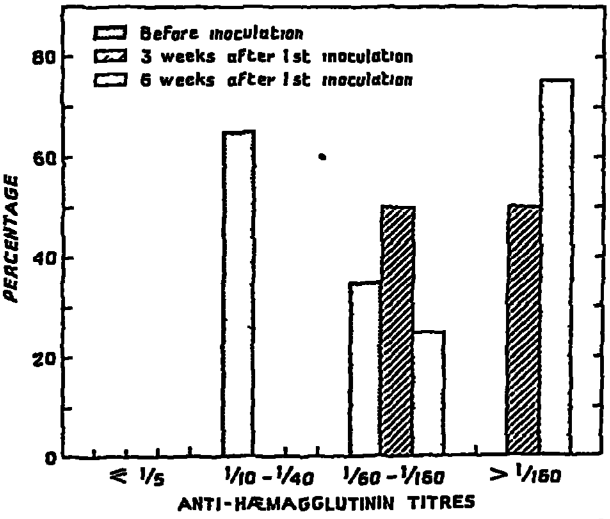

Fig 4—Distribution of titres 3 and 6 weeks after initial inoculation in 19 individuals with initial antibody titres of > 1/5, given two doses of vaccine at 3-week intervals

This, and most other serological trials, measured only hæmagglutination-inhibition antibody, and it is not known what relation this may have to protective antibody, nor indeed whether protection is due to circulating antibody or to the sensitisation of the protective mechanism—of which the antibody response may only be an indication Evidence that one injection of Asian-influenza vaccine may provide sufficient protection is given by the result of the M.R C trial, which gave a protection-rate of 52-67% immediately after vaccination, this compares well with previous trials in individuals who had previously experienced related influenza-A antigens (Commission on Influenza 1944)

Summary

A serological trial of an Asian-influenza vaccine was carried out in 83 volunteers, all of whom had been exposed to the autumn influenza epidemic 33 had had a clinical illness resembling influenza Volunteers with no initial antihæmagglutinin reacted poorly to a single dose of vaccine A much better serological response was obtained with a single dose in individuals with initial titres of 1 in 5 or more Two inoculations given to individuals without initial antibody led to a good secondary response This is contrary to previous experience, and it is suggested that two antigenic stimuli are needed to produce a good antibody response in people who have not previously experienced this antigen, whereas one is probably sufficient for those that have

Our thanks are due to Wing-Commander W Thorburn, Flight Lieutenant P Edgecombe, Mr V G Law, and Miss D Andrews for their help and cooperation, and to the Director-General of Medical Services, R A F, for agreeing to publication

We are particularly grateful to Dr F Himmelweit and the Wright-Fleming Institute for their help in production of the vaccine

The ætiological relationship of the vascular complications of diabetes mellitus to the disorder itself is the subject of much interest and controversy In a panel discussion on this problem, LeCompte (1957) has recently said that there is little evidence against the view that they may be determined by the same gene, since there are very few reported cases of capillary lesions in diabetes due to some known cause, such as pancreatitis or pancreatic fibrosis

We report here the development of a specific diabetic retinopathy and the occurrence of glomerulosclerosis of the type specific to diabetes mellitus, in a patient whose diabetes is believed to have been due to chronic pancreatitis, and we discuss the implications of these findings

Case-report

A man, aged 48, an architect, was said to have had "nephritis" following mumps in 1920, at the age of 11, and for a few years after this had experienced episodes of vague abdominal discomfort In 1928, when he was 19, he developed the classical symptoms of diabetes mellitus, was found to have considerable glycosuria, and was treated by dietary restriction and the administration of insulin Except when he had a severe infection, the daily dose of insulin varied from 28 to 40 units

In 1936 he noticed that his stools were pale and floated in water, and that he had lost weight In 1947 he complained of episodes of nocturnal diarrhœa, with the incontinent passage of pale fluid fæces In 1952 he had developed neuropathy in his legs, with absence of ankle reflexes, diminution of knee reflexes, some wasting of the calf and adductor muscles, loss of appreciation of vibration and pain, and absence of sweating in the lower limbs At this time diabetic retinopathy was first detected, a few microaneurysms and one or two round specks of hyalinisation were visible in both retinæ. In the next two years two classically painless indolent ulcers developed on his feet, he became impotent and was found to have a large distended bladder, unassociated with discomfort, which could not be voluntarily evacuated The dynamics and chemistry of the cerebrospinal fluid (C.S F) were normal and the Wassermann and Kahn reactions of serum and C.S F negative Many courses of various antibiotics were given for urinary tract infections A little protein was discovered in the urine for the first time in association with the infection In 1957, incontinence and recurrent infection became so severe that both ureters were transplanted to an isolated loop of ileum which acted as a reservoir, but in spite of this the patient died within a few months of urinary tract infection, toxæmia, and uræmia At the time of death he had moderately severe diabetic retinopathy (fig 1) During the last two years of his life his blood-pressure was about 150/105 mm. Hg, there was never any evidence of congestive heart-failure

During the thirty years of his diabetic life, hypoglycæmic episodes were exceptionally frequent, occurring up to three or four times a week, irrespective of the preparation of insulin used, and frequently required his admission to hospital During one of these admissions, in 1955, the clinical diagnosis of steatorrhœa was confirmed by fat-balance studies which showed an absorption of 60% of ingested fat, the stool contained, on average, 50 g of fat and 6 6 g of nitrogen per day Radiography of the abdomen showed extensive calcification of the pancreas (fig 2) and the results of analysis of the duodenal aspirate following the injection of secretin and pancreozymin confirmed the complete absence of exocrine pancreatic function, there being virtually no response in the pH, rate of flow, or bicarbonate, amylase, trypsin, or lipase content Subsequent treatment with pancreatin materially improved the steatorrhœa but not the nocturnal diarrhœa

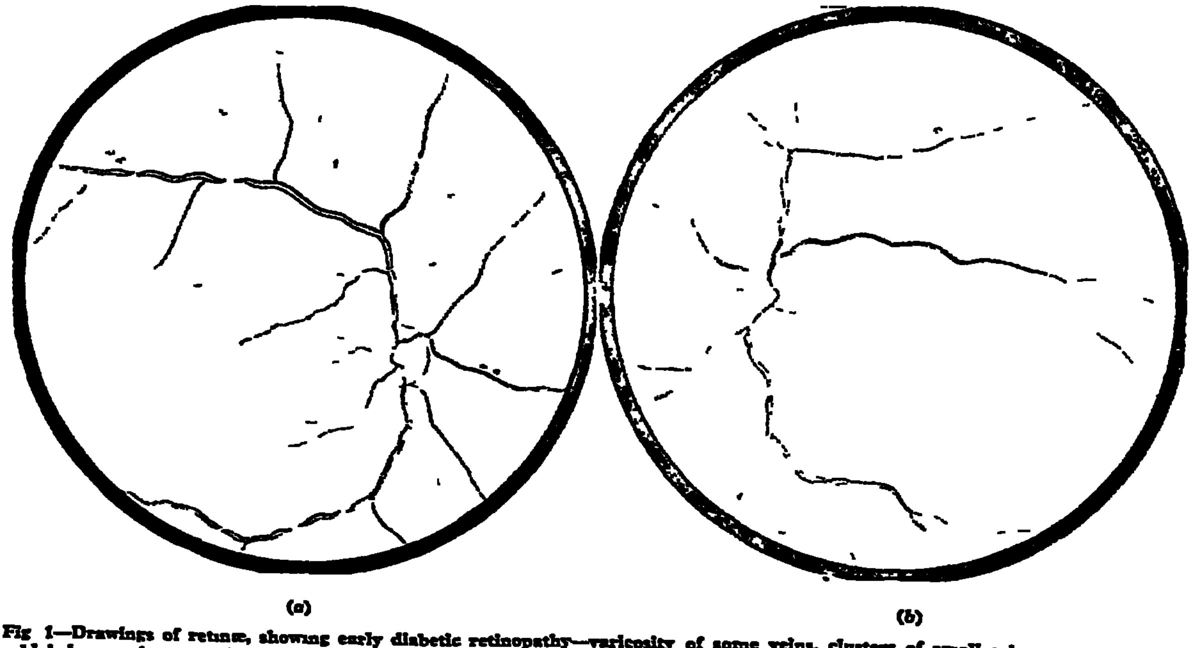
Fig 2—Oblique film of abdomen, showing calcification of pancreas

There was no family history of diabetes His parents died in their 70s, none of their parents or siblings had diabetes He had two elder brothers alive and well, and both they and the patient were of normal weight at birth

Necropsy Findings

The necropsy was carried out two hours after death

Pancreas—32 2 g (fig 3) The organ consisted mainly of fibrous tissue and nodules of calcium, very little true pancreatic tissue could be identified. The main pancreatic duct could not be found from the duodenal aspect, but in the head of the pancreas it could be seen distended by a small white calculus, 0 3 cm in diameter



(a) (b)

Fig 1—Drawings of retinæ, showing early diabetic retinopathy—varicosity of some veins, clusters of small micro-aneurysms, round blob hæmorrhages, and discrete exudates (a) right eye (b) left eye.

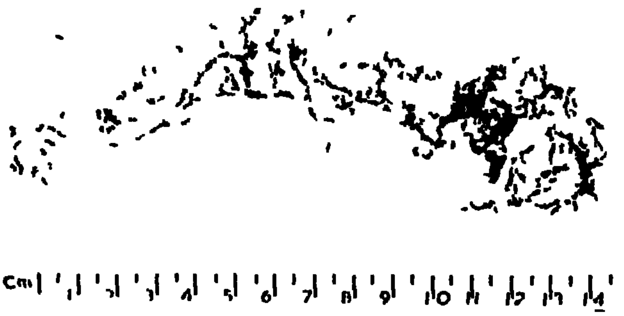


Fig 3—Pancreas, showing gross calcification

Kidneys —Right 300 g, left 225 g Both organs showed moderate hydronephrosis with chronic pyelonephritic scarring, and there were small soft calculi in the left pelvis and calyces A large perinephric abscess was found in continuity with a small abscess in the upper pole of the right kidney The perinephric abscess had tracked down the right psoas muscle into the right inguinal region and behind the pubes into the left groin

Heart —310 g There was slight left ventricular hypertrophy

Coronary arteries and aorta —These vessels contained only occasional tiny plaques of atheroma

Lungs —There was patchy collapse of the right lower lobe

Liver and bile-ducts —2080 g The organ was enlarged and congested The biliary tract was patent

Adrenal glands —Combined weight 16 7 g They were both slightly enlarged

Pituitary —0 55 g The gland was a little smaller than usual

No significant abnormalities were found in the other organs

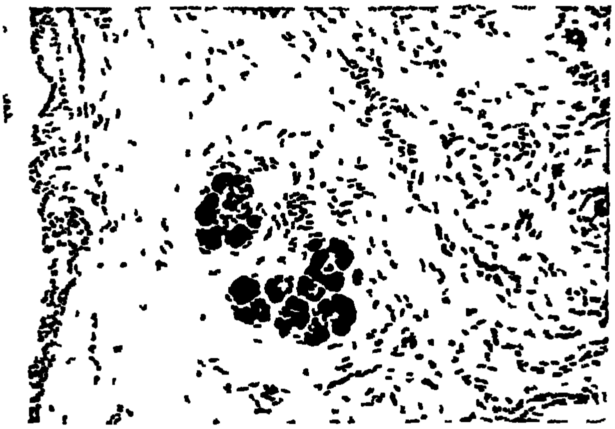

Fig 4—Pancreas, showing gross fibrosis and remaining foci of acinar tissue Squamous metaplasia is seen in a greatly dilated duct (Hæmatoxylin and eosin ×100)

Histology

Pancreas —Representative sections were taken from head, body, and tail, and stained by the hæmatoxylin and eosin method and with Gomori's chrome alum hæmatoxylin phloxine for α and β islet cells (Gomori 1941) Only occasional small islands of exocrine tissue had survived and were situated in dense fibrous tissue (fig 4) Most of the ducts and ductules were dilated and many were filled with inspissated secretion and cell debris showing varying degrees of calcification Squamous metaplasia of the duct epithelium was a feature in many areas Islet tissue was also greatly reduced in amount Small localised groups of islets were found in the fibrous tissue, and in none was there evidence of fibrosis, hyalinisation, or any other lesion associated with diabetes mellitus (fig 5)

Good differentiation of α and β cells with Gomori's stain was technically difficult because of the nature of the tissue, but as far as could be ascertained the α/β cell ratio was not abnormal

Kidneys —There was fairly extensive pyelonephritic scarring in both kidneys Many of the glomeruli exhibited diffuse intercapillary sclerosis (fig 6) and a few contained small but typical nodular lesions of classical diabetic glomerulosclerosis (fig 7) The latter varied from 20µ to 50µ in diameter There was moderately severe hyaline arteriolosclerosis

Testes —Both showed severe atrophy of the seminiferous tubules No spermatogenesis could be seen, and the tubules, whose basement membranes were considerably thickened, were lined mainly by Sertoli cells The interstitial cells were increased in number There were groups of histiocytes containing hæmosiderin in the interstitial tissue but no fibrosis or chronic inflammatory changes were seen

Heart —Early brown atrophy was present

Liver and spleen —These organs were congested

Lungs —There was purulent bronchitis, and collapse in the right lower lobe

Parotid glands —There were a few foci of fibrosis and lymphocyte infiltration, associated with glandular atrophy, but the glands otherwise appeared normal.

Adrenal and pituitary glands —No histological abnormality

Nervous system —Complete demyelination and fibrous replacement was found in peripheral nerves from the left leg and in the "presacral nerve" There was partial demyelination and fibrosis of posterior nerve-roots No abnormality of the spinal cord or brain could be seen

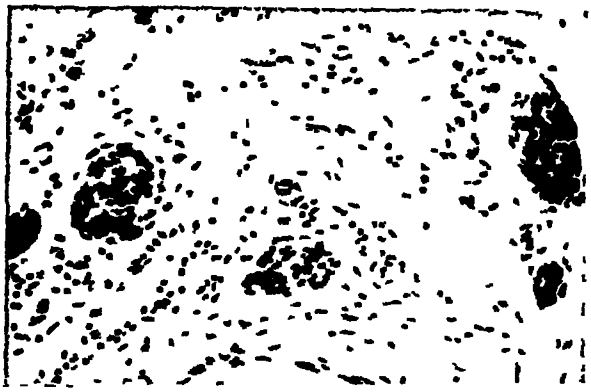

Fig 5—Pancreas showing a few islets in dense fibrous tissue (Hæmatoxylin and eosin ×175)

Discussion

The successful therapeutic use of insulin has so reduced the incidence of diabetic coma that very few diabetic patients now die from this cause (Duncan 1951) However, although the life-expectancy of the average patient with diabetes is only a few years shorter than that of the general population (Metropolitan Life Insurance Company 1947), the majority sooner or later develop one or more of the so-called degenerative changes (Mirsky 1946, Dolger 1947, Lundbaek 1954) In contrast to the neuropathic changes, the vascular lesions in the eye and kidney are generally considered to be specific to the disorder (Becker 1952, Leiter 1955, Lukens 1955) So frequently

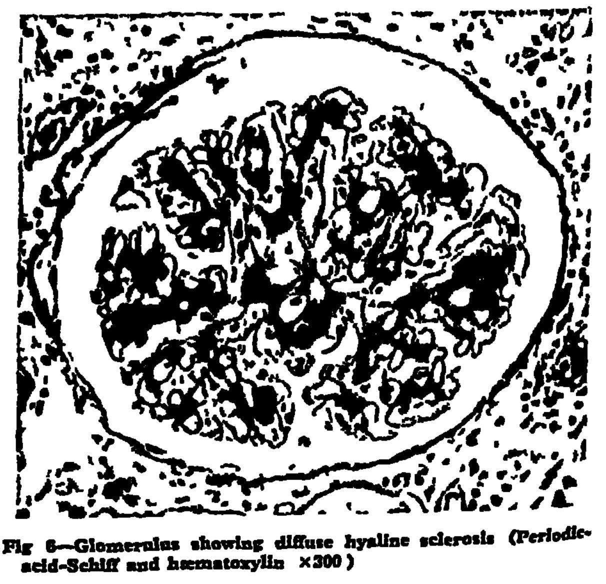

Fig 6—Glomerulus showing diffuse hyaline sclerosis (Periodic-acid-Schiff and hæmatoxylin ×300)

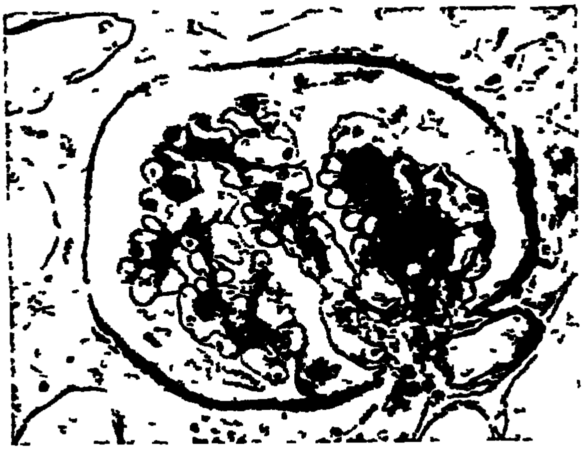

Fig 7—Glomerulus showing nodular lesion of classical diabetic glomerulosclerosis (Periodic-acid-Schiff and hæmatoxylin ×300)

do these changes accompany longstanding and poorly controlled diabetes that some authorities look upon them as an integral part of the disease rather than as complications of it (Dolger 1947, Henderson et al 1947)

There is little doubt that the predisposition to diabetes mellitus is often inherited, being most probably transmitted as a recessive characteristic, though it manifests itself clinically in only a proportion of those bearing the gene (Steinberg 1955) The tendency to develop the specific vascular changes could similarly be inherited, but the fact that they have not been found with certainty in persons having no demonstrable defect of carbohydrate metabolism (Becker 1952, Mirsky 1952) makes it improbable that they are inherited as an independent diathesis For the same reason, even if they were transmitted in close association with the diathesis of idiopathic diabetes (Dry and Hines 1941, White and Waskow 1948, LeCompte 1957), their development must depend on the presence of the metabolic disturbance of diabetes, of which the abnormality in carbohydrate metabolism may be only a part

Reproduction of the lesions of the specific retinopathy or nephropathy in animals made hyperglycæmic by one or other of a variety of techniques would demonstrate that a hereditary basis is not necessarily involved Such attempts have not been unequivocally successful (Lukens and Dohan 1946, Foglia et al 1948, Friedenwald 1950, 1952, Mann et al 1951, Becker 1952, Rickets 1952, Janes and Bounds 1954, LeCompte 1957) Nevertheless, these were short-term experiments, and it may be that the duration, as well as the degree of control, of the diabetes favours the development of these retinal and glomerular changes in man

Hyperglycæmia, impaired glucose tolerance, and the tendency to develop ketosis can arise in man as the result of disease of the pancreas The development of the specific retinopathy or nephropathy in such "pancreatic diabetics" would support the view that these complications result from the abnormal metabolism in diabetes rather than as a consequence of an inherited defect So far as we know, only two such cases have been previously reported

Sprague (1947) described a patient who developed relapsing pancreatitis at the age of 27 and became diabetic eight years later After a further nine years he was found to have a specific diabetic retinopathy

The presence of diabetic retinopathy was recorded by Hudson (1953) in a man, aged 50, suffering from hæmochromatosis who had developed diabetes fifteen years previously

Three other cases are described in personal communications

Stawell, in a personal communication to Lawrence (1949), mentions diabetic retinopathy in a patient with diabetes due to hæmochromatosis, Rynearson (1957) describes a patient who developed diabetic retinopathy three years after the onset of diabetes which followed total pancreatectomy, and Dunlop (1957) records the presence of the specific retinopathy in a patient with longstanding diabetes resulting from hæmochromatosis

The details of Stawell's patient are not known, but in none of the other patients was there a family history of diabetes, and the diabetes was regarded as purely pancreatic in origin

We believe that the diabetes in our patient was also a true "pancreatic diabetes," there being several clinical features which suggested that his diabetes was due to insulin lack alone rather than to the operation of any anti-insulin mechanisms

(1) The sensitivity to the blood-glucose-lowering action of insulin (his blood-glucose was noted on several occasions to fall from over 600 mg to less than 50 mg per 100 ml four to six hours after the subcutaneous injection of 12 to 20 units of soluble insulin), this probably accounted for the extraordinary frequency of the hypoglycæmic episodes, even with a moderate daily dose which varied from 28 to 40 units, except when infection necessitated the administration of larger doses This tendency to hypoglycæmia remained unaltered throughout the entire course of his disorder

(2) His failure to show any reduction in the concentration of glucose in the blood in response to a dose of 4 5 g of carbutamide by mouth the immediate hypoglycæmic effect of carbutamide is believed to be due to the release of insulin from the β-cells of the pancreas, and its absence in this patient suggests that the pancreas was unable to secrete insulin (Houssay and Phenos 1956, Fajans et al 1956)

(3) The clinical and biochemical evidence of extensive disease of his pancreas was overwhelming With duodenal intubation no exocrine secretion could be demonstrated in response to stimulation by secretin and pancreozymin, and the stool nitrogen content was elevated The steatorrhœa thus appears to have been of pancreatic origin From the patient's observation, pale stools were present eight years after the onset of the diabetes, and this suggests that disease of the pancreas was present at that time The ætiology of the pancreatic lesion is, however, obscure Mumps contracted at the age of 11 may have some causal relationship, and the history of vague episodes of abdominal discomfort during adolescence suggests that pancreatitis had already developed Diabetes may precede the steatorrhœa, and not uncommonly develops within a few years of the first attack of pancreatitis (Maimon et al 1948)

(4) Finally, the fact that, as far as can be ascertained, none of his known relatives has or had diabetes, is consistent with the view that he had not inherited a diabetic diathesis

The clinical diagnosis of severe pancreatic insufficiency was confirmed by the finding of gross pancreatic fibrosis at necropsy The reduction in the amount of islet tissue from the normal appears quite sufficient to account for the patient's diabetic state on the basis of insulin deficiency The hypothesis that he might have had a coincidental diabetic diathesis is not supported by the histological appearance of the few remaining islets No hyalinisation or other lesion associated with idiopathic diabetes mellitus could be found, and the proportion of α to β cells seemed to be within normal limits (MacLean and Ogilvie 1955) The appearance of the pancreas was consistent with pancreatitis due to mumps The presence of the calculus in the main pancreatic duct is probably not of ætiological significance, since marked calcification was scattered throughout the pancreatic tissue and in most of the ducts

It was unfortunately not possible to examine histologically the retinopathy visible on clinical examination, but the latter is sufficient to establish its specificity The presence in the kidneys of typical Kimmelstiel-Wilson bodies was established by the histological examination, though they were few - The diffuse glomerulosclerosis was also thought to be diabetic in nature and to conform to the descriptions by Bell (1953) and Lambie and MacFarlane (1955) It is, however, not as specific to diabetes mellitus as the nodular lesion, since similar changes may be found in type-II glomerulonephritis

The problem of the relationship between diabetes and the later development of its specific complications will probably remain unsolved until a more intimate knowledge of the biochemical abnormality in diabetes and in the tissues affected by the degenerative changes is available Nevertheless, the development of these changes in patients whose diabetes appears to be of pancreatic origin is very strong evidence in favour of the view that they are to a large extent the consequence of the metabolic disorder which results from insulin deficiency Reports of patients similar to our own would be of great value in throwing further light on this problem, which is not merely an academic one The emphasis commonly placed upon the need for rigid diabetic control will be fully justifiable only if it can be shown that the development of these complications is dependent on or influenced by a derangement of metabolism, and that they are not an inescapable consequence of inheritance

Summary

The precise relationship between the development of the specific vascular complications of diabetes mellitus in the retinæ and of specific nodular glomerulosclerosis to the disorder itself is unknown A patient has been described in whom both these complications occurred and in whom there was overwhelming evidence to support the view that the diabetes arose as a result of pancreatic disease The significance of this case in relation to present-day views of the ætiology of these complications is discussed It constitutes strong evidence in favour of the view that these complications are the consequence of the metabolic disorder which results from insulin deficiency

For permission to report this case we are grateful to Prof D M Dunlop and Sir Stanley Davidson, in whose charges the patient was investigated We thank Prof G I Scott and Miss C Gundry for the ophthalmoscopic examination and drawings, Dr I N Marks who carried out the tests of the pancreatic function, and Mr T C Dodds, of the department of medical photography, for the photographs

TWENTY-NINE CHILDREN WITH SULPHONAMIDE HÆMATURIA

Gavin C Arneil
M D Glasg, M R C P, F R F P S, D C H
LECTURER IN CHILD HEALTH IN THE UNIVERSITY OF GLASGOW, PÆDIATRICIAN, ROYAL HOSPITAL FOR SICK CHILDREN, GLASGOW, C3

Shortly after the introduction of sulphonamide therapy, hæmaturia was noted as an occasional complication

The explanation seemed to be that, as urine passes along the renal tubules, it becomes more concentrated and acid, with the result that crystals of sulphonamide may be deposited The convoluted tubules are first affected (Goodman and Gilman 1955), but deposition of crystals can spread in either direction and give rise to hæmaturia, albuminuria, oliguria, hypertension, or nitrogen retention Such cases may present with anuria (Atkinson 1957, Browne 1957) or more rarely with obstruction of the urethra (Miller and Mitchell 1952, Rice-Edwards 1950) These happenings may be attributable to overdosage of sulphonamide, inadequate intake of fluid, or the use of a preparation unduly liable to crystallise out at pH values found in the renal tubules

In the ten years since 1948, a total of 29 patients have been treated in the medical wards of The Royal Hospital for Sick Children, Glasgow, for hæmaturia associated with taking sulphonamide drugs In all of them

1 The patient had had sulphonamide therapy before the symptoms began
2 There were no history or subsequent findings suggestive of renal disease (except those occasioned by sulphonamide crystallisation)
3 Gross hæmaturia and crystalluria were present

The presence of urinary sulphonamide was confirmed in almost all cases and the serum sulphonamide level estimated in some

Clinical Observations

The ages of the 29 children ranged from 1 to 12 years, most being between 1 and 6 Sulphonamide had been given for periods of one to six days in daily doses of 100–400 mg per kg body-weight The blood-pressure was elevated in 14 of the 22 cases in which it was recorded, but it returned to normal levels within a few days The non-protein-nitrogen content of the blood was raised on 13 of the 21 occasions in which the estimation was made The hæmaturia lasted one to six days, and albuminuria usually persisted a few days longer

In 3 cases anuria persisted for more than forty-eight hours, uræmia was present in all three

Case 1 —A girl, aged $6^1/_2$, was given sulphamerazine 2 g daily for two days because of upper respiratory infection She then complained of loin pain, and developed hæmaturia followed by anuria After forty-eight hours' anuria her blood-pressure rose to 148/110 mm Hg, and she had severe convulsions—probably due to hypertensive encephalopathy The blood non-protein nitrogen was 125 mg per 100 ml

Lumbar puncture, venesection, sedation with phenobarbitone, and hypertonic solutions intravenously were employed before her convulsions ceased She was given sodium bicarbonate gr 180 daily, and diuresis began shortly after this was started Within fourteen days she was symptom-free

Case 2.—A boy, aged 2, was given four doses of sulphamerazine, each 0 5 g orally, as treatment for a sore throat. He vomited, and developed hæmaturia and anuria Anuria persisted for seventy-two hours, during which time the blood non-protein-nitrogen rose to 140 mg per 100 ml and the blood-pressure to 114/80, and he became fevered Sodium bicarbonate gr 180 daily was given and fluid intake restricted to 1 litre daily Diuresis began and he became symptom-free ten days later

Case 3—A girl, aged 2, was given 2 5 g of sulphamerazine daily for four days for a respiratory infection She then passed "grains of sand" per urethram, and stopped passing urine Sixty hours later she was admitted to hospital; the urethra was cleared and she voided urine Treatment was begun with sodium bicarbonate gr 180 daily She had anuria for a further forty-eight hours, during which time she was restless and anorexic, and her blood-urea rose to 147 mg per 100 ml Her blood-pressure was 150/70, her serum-sodium level had fallen to 114 mEq per litre and serum-potassium to 3 8 mEq Supplementary potassium was added to her intake of 250 ml of 25% glucose solution daily, and diuresis began after five days of anuria This urine contained erythrocytes and sulphonamide and her serum-sulphamerazine content was 13 8 mg per 100 ml, more than a hundred hours after oral therapy had stopped

As the following table shows, 27 of these 29 children had been given a preparation containing sulphamerazine

Drug	No of cases	Dosage mg per kg per day
Sulphamerazine	26	100–400
Sulphasomidine	1	200
Sulphadimidine	1	?
Triple sulphonamide *	1	210

* A mixture of sulphamerazine, sulphathiazole, and sulphadiazine.

One specific brand of aqueous suspension was prescribed for 22 of these 27 cases In 13 the dose of sulphamerazine had been 100–200 mg per kg per day, in 7 it had been 200–400 mg per kg per day, and in the remainder indeterminate

Our treatment in these cases was essentially conservative Administration of sulphonamide was stopped, and, where excretion of urine was adequate, copious fluids were given together with sodium bicarbonate gr 30 four-hourly When anuria and uræmia arose, fluid intake was restricted and glucose administered Hypertensive encephalopathy was treated by sedation, lumbar puncture, and venesection

This cautious approach to treatment seems justified in that all cases to date have recovered completely

Discussion

The dosage of 'Cremomerazine' recommended by the manufacturers for the first four years of life amounts to about 110–220 mg per kg for the first day and about 70–140 mg per kg per day thereafter (dosage refers to sulphamerazine content) It is disturbing to find that 13 of the present patients were receiving doses which approximated to such levels of dosage, though in most cases the drug had been given more frequently than twelve-hourly 1 boy had received only 2 g (190 mg per kg) when anuria began There is no evidence that the fluid intake of these children was restricted It may be true that, under ideal conditions, with twelve-hourly doses and copious fluid and alkali administration, sulphamerazine seldom produces hæmaturia, but the overriding consideration here is that in actual practice this drug may cause hæmaturia, azotæmia, and hypertension in children when given at a dosage level in frequent use To justify giving a drug potentially noxious in therapeutic doses one must show that it has significant advantages over other preparations Sulphamerazine seems to me to have no outstanding virtue which would lead me ever to prescribe it.

Many cases of sulphamerazine hæmaturia have been reported (Sheppard 1948, Atkinson 1951, Brand 1951, Rendle-Short 1951, Morton and Dobbs 1951), but probably many more cases with slight hæmaturia have not been recognised There is a risk that hæmaturia following the treatment of upper respiratory infections with sulphamerazine might simulate acute hæmorrhagic nephritis and so mislead the clinician -

Summary

29 cases of hæmaturia following administration of sulphonamide drugs are recorded Anuria, hypertension, encephalopathy, and uræmia were seen in some patients, but all subsequently recovered

27 of these patients had been given sulphamerazine, and in many cases the dose was not excessive as judged by one manufacturer's recommendations It seems doubtful whether the use of this drug is justified.

I should like to thank Prof Stanley G Graham and Dr J H. Hutchison for allowing me to use their case-records

METHOD OF ESTIMATING THE DIAMETER OF ERYTHROCYTES

PER STAVEM
M D Oslo
RESIDENT HOUSE-OFFICER,
MEDICAL DEPARTMENT OF ST JOSEPH HOSPITAL, PORSGRUNN, NORWAY

THE diameter of the erythrocytes can be measured by many methods, most of which are rather laborious and require special equipment. A fairly simple method, requiring no special equipment, is to spread a blood film from a normal control on top of a stained film with the erythrocytes to be measured, and then to compare the relative sizes of stained and unstained erythrocytes This method has for many years been occasionally used in Norway, and undoubtedly in many other countries Bessis (1956) mentions the method, giving Pittaluga the credit for introducing the method to him

This method of superimposed blood films has, however, certain drawbacks it is difficult to make both films thin enough in the same places to avoid overlapping of stained and unstained erythrocytes, the stained film is often scratched when the superimposed unstained film is being spread, and the process of staining might change the

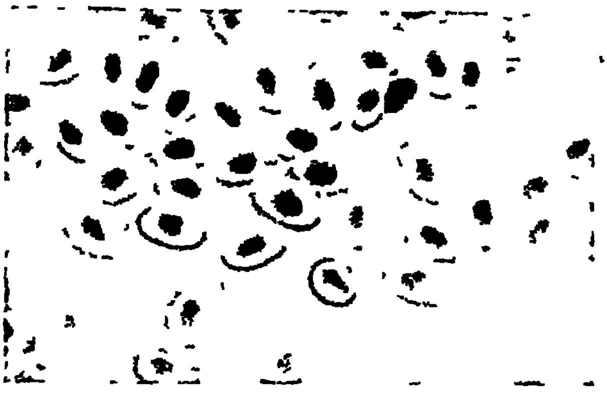

Fig 1—Hens' erythrocytes

size of the erythrocytes—but this change in size is usually surprisingly small.

All these difficulties would be avoided if one could mix blood from the unknown and the control before spreading the film and still be able to decide which erythrocytes in the film belonged to the unknown and which to the normal control. Erythrocytes of birds are elliptical and contain a nucleus—features which clearly distinguish them from human erythrocytes. We have lately made films from a mixture of hens' blood and human blood and have estimated the size of the human erythrocytes by comparing them with the hens' erythrocytes.

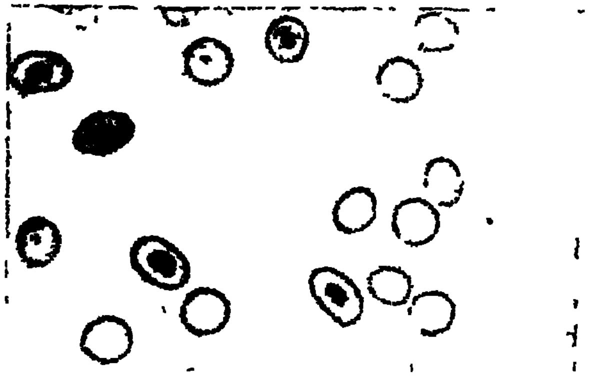

Fig 2—Mixture of normal human and hens' erythrocytes

Heparinised blood is collected from a killed hen and may be kept in the refrigerator for days or weeks until needed. Two drops of hens' blood is added to 0·5 ml. of heparinised or oxalated human blood, and a film is made from the mixture and stained with Wright or Giemsa stain. Hens' erythrocytes are elliptical, with a longitudinal diameter of about 11·0 μ and a lateral diameter of 6·7 μ (90% of hens' erythrocytes have a longitudinal diameter between 9·8μ and 12·2μ, and 90% have a lateral diameter between 5·8μ and 7·6μ). The size of a particular hen's erythrocytes is checked against a normal human control before the hen's blood is used for estimating the size of human erythrocytes.

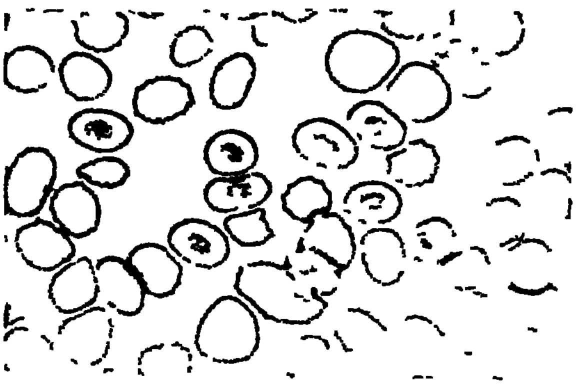

Fig 3—Mixture of human erythrocytes from a patient with pernicious anæmia and of hens' erythrocytes

If one does not want to keep a supply of hens' blood in the refrigerator, two drops of blood is easily obtained from a cut in a hen's comb.

Fig. 1 shows a stained film of hens' blood, fig. 2 a film made from a mixture of hens' blood and normal human blood, and fig. 3 a film from a mixture of hens' blood and blood from a patient with untreated pernicious anæmia.

LEICESTER GENERAL HOSPITAL

Placenta prævia may present as either antepartum hæmorrhage or (without antepartum hæmorrhage) as malpresentation, unstable position, or a high fœtal head. The modern management of placenta prævia has drastically reduced maternal and fœtal mortality (see table).

Expectant treatment (Macafee 1945, 1946, Johnson 1945, 1950, Grant 1955) aims to continue the pregnancy into the 37th week, when the fœtus has every chance of surviving. The patient has to be admitted for 1–6 weeks before a low implantation of the placenta can be excluded or confirmed. Under anæsthesia the lower uterine segment is examined digitally through the cervix. If the placenta is then detected anterior to but not beyond the internal os of the uterus, the membranes are ruptured, but if it is palpable in any other position, immediate lower-segment cæsarean section is the treatment of choice. If the placenta is not palpable, the pregnancy may be allowed to terminate spontaneously.

Our object was to find a reliable simple diagnostic method, so that those patients who were conclusively found not to have a placenta prævia could be spared a long stay in hospital. We wished to avoid both unnecessary filling of valuable hospital beds and the emotional strain experienced by many mothers because of enforced absence from their homes and families, as well as the taking of numerous radiographs for localising the placenta; this may be dangerous because of irradiation of the fœtus (Stewart et al. 1956) and the mother (Medical Research Council 1956), and is expensive in film and the time of highly skilled staff.

We have investigated the accuracy and practical value of a single lateral radiograph of the uterus in cases of suspected placenta prævia.

---

* Home address: 414, Atlantic Avenue, Winnipeg 4, Manitoba, Canada.

Material and Methods

107 patients were investigated between January, 1953, and June, 1956 The position of the placenta was estimated radiographically *only* if the information would help in the clinical diagnosis Antepartum hæmorrhage, malpresentation, unstable lie, or high fœtal head were the indications for radiography

The apparatus consisted of a standard four-valve X-ray unit with a rotating anode tube and tilting table

Three radiographs were taken routinely in each patient These were lateral views of the uterus, the pelvis in the erect position, and the pelvis in the semi-erect position

The films were read on a standard viewing-box Separate illumination by a 100-watt bulb was necessary for viewing the anterior aspect of the uterus and adjacent abdominal wall. A wedge filter was not used while taking the radiographs

Various radiographic techniques have been developed to find the position of the placenta Soft-tissue radiography (direct placentography) has proved the most valuable (Snow and Powell 1934, Dippel and Brown 1940, Bishop 1945, Reid 1949, 1951, 1953, Stallworthy 1950, 1951, Murray 1953, Hartley 1954, Dawson and Mitchell 1954) Further information is obtained by radiographic measurement of the displacement of the fœtal head from the sacral promontory and symphysis pubis at the pelvic brim (indirect placentography) (Ball and Golden 1941, McCort et al 1944, Bishop 1945, Reid 1951)

Cystography (Ude et al 1934, Dippel and Brown 1940) is not generally used now because it is unreliable

Amniography (Menees et al 1930, Kerr and McKay 1939, Savignac 1953, Williams 1956), aortography (Hartnett 1948), retrograde femoral arteriography (Sutton 1952), and localisation of the placenta by radioactive sodium (Browne 1951) are experimental techniques

Both direct and indirect placentography were used during this investigation As a precaution, the patient was asked to empty her bladder and rectum before being radiographed

Results

The placenta was correctly identified in the upper uterine segment in 90 of the 107 cases At the beginning of the investigation the placenta in 1 of the 107 cases was wrongly interpreted as entirely in the upper segment, examination under anæsthesia revealed a second-degree anterior placenta prævia

Using soft-tissue and displacement radiographic techniques, placenta prævia was missed in 3 cases, and correctly diagnosed in 12 cases, the radiographic findings were inconclusive in 2 cases It was observed that, if there was no placental shadow in the upper uterine segment, placenta prævia was likely to be found clinically In practice, these patients must be admitted, most have placenta prævia

Of the 90 cases in which the placenta was correctly identified in the upper uterine segment, 54 were associated with antepartum hæmorrhage The causes of antepartum hæmorrhage were analysed as follows

No cause found	30	Erosion of cervix *	3
Abruptio placentæ	16	Varicosities of cervix	1
Circumvallate placentæ	3	Polyp of cervix	1

* 1 case proved to be invasive carcinoma of the cervix

Discussion

The most significant conclusion reached was that radiological evidence of the placenta in the upper uterine segment is highly accurate, a lateral radiograph of the uterus taken after 34 weeks' gestation, in the absence of hydramnios, yielded the necessary information to exclude placenta prævia It was found that the management of 90 out of the 107 patients investigated could have been decided with accuracy on the evidence of single lateral radiograph of the uterus

MORTALITY-RATES IN PLACENTA PRÆVIA

Treatment	Series	Maternal mortality (%)	Fœtal mortality (%)
Active (pre-modern)	Berkeley (1936) Browne (1939)	7 0 5 9	59 0 54·0
Modern with expectant	Macafee (1945) Grant (1955)	0 57 0 00	23 5 9 9

Therefore, we felt it was safe to allow the patient to go home from hospital when placenta prævia had been excluded radiographically In a woman who has had antepartum hæmorrhage, the os should be inspected through a speculum after a week's rest, to exclude lesions of the cervix, she is then allowed to return home We have latterly adopted this procedure without regrets Chassar Moir (1956) supports this view

> " If in a case of antepartum hæmorrhage a low implantation of the placenta can be excluded, the patient can be spared the necessity of a vaginal examination, and can, after a week's rest, be allowed to return home without fear of renewed, violent hæmorrhage "

Summary

Radiographic evidence of the placenta in the upper uterine segment is highly accurate A single lateral radiograph of the uterus after 34 weeks' gestation is enough to exclude placenta prævia

Of 107 patients investigated by direct and indirect placentography (soft-tissue radiographs and measurement of the displacement of the fœtal head), 17 had placenta prævia, which was diagnosed correctly in 12 cases and suspected in 2

A lateral uterine radiograph requires no special skill or equipment, but transillumination of the film by a 100-watt bulb may be needed to detect the anterior wall of the uterus and the abdomen One such radiograph is compatible with good obstetric standards, irradiation to the fœtus and mother is minimal, film costs are reduced, and fœtal abnormalities may also be detected

X-ray location of the placenta in the upper uterine segment relieves the patient's anxieties for she can be sent home without fear of violent hæmorrhage, and hospital beds are not filled unnecessarily

Preliminary Communications

NUCLEAR CHANGES IN ORAL EPITHELIUM IN PERNICIOUS ANÆMIA

EPITHELIAL atrophy of the tongue is said to occur in about 70% of cases of pernicious anæmia,[1] but little study has been made of the response of the tongue to specific treatment An attempt was therefore made to examine cytological material from the tongue, but preparations were unsatisfactory, probably because of the heavy keratinisation of the epithelium Examination of oral mucosa from the inside of the cheek has, however, proved more satisfactory and a study of nuclear abnormalities and changes in size has been made in patients with pernicious anæmia

Changes in gastric columnar cells in pernicious anæmia have been reported by Massey and Rubin,[2] while desquamated squamous cells present in gastric aspirate were examined by Graham and Rheault [3] They measured the greatest cytoplasmic diameter and found it increased Recently Boen [4] has described nuclear changes in exfoliated squamous cells from the mouth and has made comparative measurements of the longer axis of the nucleus In seven out of his ten patients with pernicious anæmia, enlarged squamous-cell nuclei were seen and the nuclei were restored towards normality by specific treatment The three cases with relatively normal nuclei were excluded from this comparison Morphological abnormalities of the nucleus, and in particular a reticulated chromatin structure, were found to disappear during treatment A series of normal controls matched according to age were also examined by Boen

In the present study, preparations of oral mucosa have been taken by scraping the inside of the cheek with a microscope slide Thirty-nine cases of pernicious anæmia have been studied in this way and similar changes of nuclear size and morphology noted Twenty-five of these cases have been re-examined later at periods varying from 2 to 32 months from the date when they were first diagnosed and treated, and in twenty-two of these there has been evidence of diminution in nuclear size In all cases 100 nuclei have been measured in both longer and shorter axes, and the averages of these measurements used for comparison

Material from ninety-five normal controls of varying ages has also been examined by the same technique By relating nuclear size to age (see figure), a surprising increase of the shorter axes of the nuclei becomes evident The effect is obvious only over the age of 60, and if normal controls of 60 years and over be compared with the rest a significant difference arises ($P<0\ 05$) For this reason, the results from cases of pernicious anæmia have been compared for each axis within two age-groups—35–59 years, and 60 years and over

TABLE I—MEAN AXIS MEASUREMENTS IN PERNICIOUS ANÆMIA AND CONTROLS

Cases	Age range	No	Mean and standard error		Standard deviation	
			Longer axis	Shorter axis	Longer axis	Shorter axis
Pernicious anæmia	35–59	17	12 127± 293	9 496± 231	±1 210	±0 953
	60+	22	12 342± 202	9 618± 203	±0 945	±0 950
Normal controls	< 35	33	11 709± 117	8 435± 127	±0 670	±0 728
	35–59	41	11 636± 091	8 558± 108	±0 582	±0 694
	60+	21	11 920± 112	8 930± 123	±0 512	±0 561

TABLE II—PERNICIOUS ANÆMIA AND CONTROLS ANALYSIS OF RESULTS

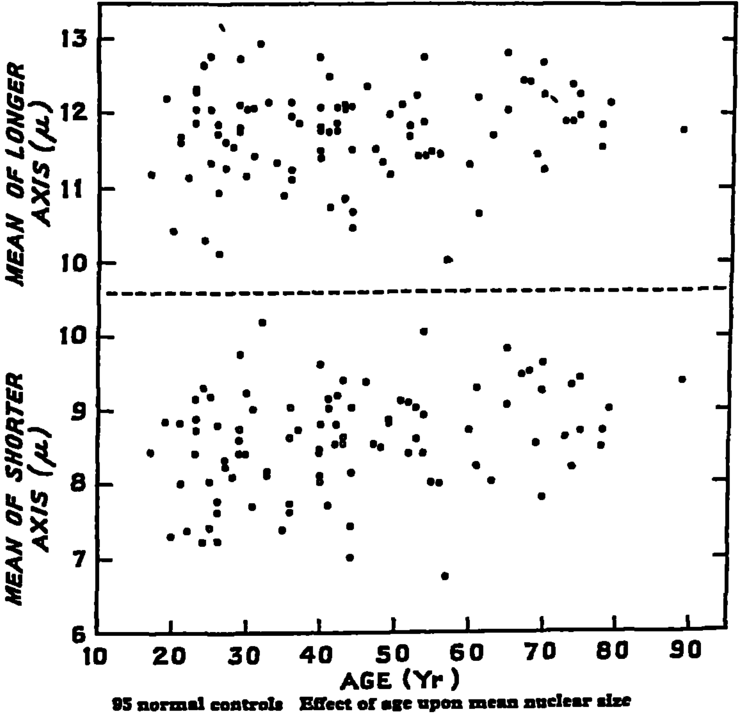
Age range	t		P	
	Longer axis	Shorter axis	Longer axis	Shorter axis
35–59	1 60	3 68	not signif	< 0 001
60+	1 83	2 91	not signif	< 0 01

When all thirty-nine cases of pernicious anæmia, including those few with relatively normal nuclear size, are compared with their controls in the two age-groups, it becomes apparent that measurements in both axes in pernicious anæmia are greater than in controls (table I) This apparent increase in size in the pernicious anæmia nuclei falls just short of significance level for the longer axis, but is highly significant for the shorter (table II) The degree of significance is less for the over-60 age-group and this appears to be due to the effect of age upon the normal controls

Ten cases of normocytic normochromic anæmia have also been examined and the nuclear size has been found to lie within the normal range Groups of controls with achlorhydria and oral sepsis show no significant departure from the normal

One patient with a smooth tongue in the absence of anæmia, with a normal level of serum-iron, and with free acid in the stomach was found to have abnormally large squamous-cell nuclei which reverted towards normal with oral administration of vitamin-B complex Results in iron deficiency are being studied

One may conclude therefore that squamous-cell nuclei from the mouth are abnormally large, particularly in the shorter axis, in pernicious anæmia, and that they revert



95 normal controls Effect of age upon mean nuclear size

CLINICAL DEXTRAN FOR ACUTE EPISODES IN PAROXYSMAL NOCTURNAL HÆMOGLOBINURIA

IN 1955, Pillemer[1] described properdin as a natural immune property of serum, and later Hinz et al [2] brought forward evidence that the hæmolysis of the red blood-cells in paroxysmal nocturnal hæmoglobinuria was due to the interaction of properdin with the stroma of the intact red cells

One of us (F S) found that, in some healthy persons of blood-group O, the properdin titre differed according to the temperature at which the red cells are separated from the serum. In these people, if whole defibrinated blood was used and the mixture allowed to stand at 0°C $1^1/_2$ hours, the properdin titre was altered, and in some cases a much lower titre was obtained than when the serum was separated from the blood at 37°C immediately after it had been collected If, before the whole defibrinated blood was cooled to 0°C, certain substances, including clinical dextran, were added in suitable concentration, the subsequent cooling of the mixture to 0°C did not decrease the properdin titre

Dextran was, to some extent, anticomplementary and was also one of several substances which, in certain concentrations, prevented the activity, in most cases, of any previously existing cold incomplete anti-H antibody There are many explanations of the interference with the properdin content of the serum associated with the incubation of group-O blood with its own cells at 0°C in these cases, one is the possibility that it is associated with the union of cold incomplete anti-H antibody with the red cells at this temperature This relationship is being worked out, and further details will be published later

These laboratory investigations suggested that clinical dextran might be valuable for the control of the acute episodes of paroxysmal nocturnal hæmoglobinuria, so it was tried in two cases

Case 1 —A man with typical paroxysmal nocturnal hæmoglobinuria had been under observation in the department of hæmatology for $2^1/_2$ years and occasionally had to be admitted because of acute episodes of hæmoglobinuria that sharply lowered his hæmoglobin level Such episodes were usually treated by blood-transfusions, but in one of them infusions of clinical dextran were substituted for blood-transfusion The dextran infusions were effective, and the hæmoglobinuria ceased, but it recurred some time after the dextran infusion had stopped

Case 2 —A married woman with typical paroxysmal nocturnal hæmoglobinuria was under the care of Dr M L Thomson of Salford Royal Hospital She had been under observation for many years, and the present attack of hæmoglobinuria had lasted 6 weeks She was admitted to hospital, and her hæmoglobin was 7 5 g per 100 ml Clinical dextran 1 litre was infused, and next morning her urine contained no hæmoglobin Next day she had a transfusion of packed washed cells, which was followed by pyrexia and a rigor, and some hæmoglobinuria returned, with failure of the hæmoglobin to increase by the expected amount. On the day after the transfusion the patient was infused with clinical dextran 500 ml, and this was followed by considerable diminution in the hæmoglobinuria, which in two or three days disappeared altogether Her hæmoglobin on leaving the hospital was 8 g per 100 ml When she attended the outpatient department ten days later, her hæmoglobin was 9 5 g per 100 ml, and there had been no recurrence of hæmoglobinuria

It is, of course, well known that hæmoglobinuria developing in paroxysmal nocturnal hæmoglobinuria will sometimes stop spontaneously The results we have obtained are suggestive, but it is clear that the treatment could be tried on more patients Since individual physicians rarely see more than one or two cases, we are publishing this report at an early stage in the hope that others will be interested in trying the infusion of dextran during an acute episode of paroxysmal nocturnal hæmoglobinuria

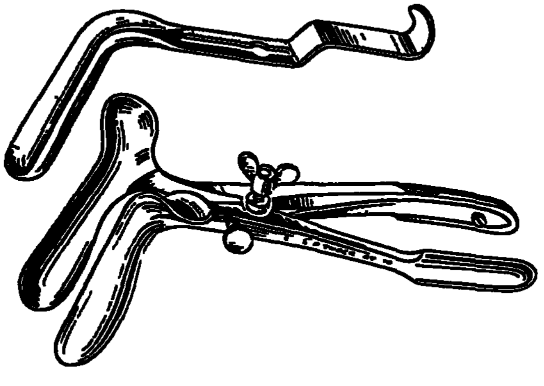
New Inventions

THREE-BLADED SPECULUM FOR INTERNAL ANAL SPHINCTEROTOMY

THE treatment of chronic anal fissures by deliberate division of the internal sphincter is the method favoured by an increasing number of surgeons For its accurate performance a speculum is required which separates the anal margins and exposes the posterior wall of the anal canal for incision Some variety of bivalve speculum is commonly used for this purpose, but in my experience this has not always given entirely satisfactory access, and I have recently designed a three-bladed speculum which I think has certain advantages (see figure)

The instrument has two main lateral blades, to each of which a handle is attached at one end almost at right-angles to the axis of the blade The two handles are connected at a pivot $1^1/_2$ inches from the blades Normally the two handles are kept apart by a spring which brings the blades of the instrument into firm apposition The coopted blades form a smooth and more or less cylindrical mass of metal which has a conical tip like a fairly narrow tubular proctoscope and



is easily introduced into the anal canal Once the speculum is in position with its handles lying anteriorly, the blades are separated by approximating the handles gradually against the resistance of the spring When the required degree of separation has been achieved it can be maintained by tightening a distraction screw

In many cases this manœuvre by itself gives an excellent view of the posterior anal wall, sufficient for sphincterotomy In some patients, however, internal hæmorrhoids are present in addition to the fissure, and the right anterior pile tends to bulge into the lumen between the front edges of the lateral blades To overcome this difficulty a third (anterior) blade has been devised to retract this wall strongly forwards It is attached by a handle to the pivot of the speculum, and when in place it always provides untrammelled access to the posterior wall and its fissure

Another feature of this speculum is that each of its three blades is slightly waisted near its external end When the expanded instrument is in situ, the anal sphincters grip this waist so that, by downward traction in an axial direction, the surgeon can to some extent draw the internal sphincter out of the anal canal and render its distal portion specially prominent for division

Though this speculum was designed primarily for internal sphincterotomy, it also affords ideal exposure for other fairly common operations—e g , removal of hypertrophied anal papillæ under local anæsthesia in the outpatient department, and for diathermy of benign tumours of the extreme lower end of the rectum It is also admirable for submucosal hæmorrhoidectomy according to the technique advocated by Parks [1]

The speculum was made to my specification by Messrs Charles F Thackray, of Leeds

Reviews of Books

The Extra Pharmacopœia

24th ed Vol I London Pharmaceutical Press 1958 Pp 1695 £3 5*s*

IT is seventy-five years since the first edition of Dr Martindale's *Extra Pharmacopœia* appeared, and the fact that it is now in its 24th edition testifies to the esteem in which it is held the world over The many new remedies introduced in the past six years have made the new edition much bulkier than any of its predecessors Because " Martindale " is a book of reference and not a textbook, information about older drugs, even though now seldom used, must be retained Some sections have indeed been pruned, but the omissions are few compared with the additions The main titles of drugs are now in English instead of Latin—a change that conforms with the practice now followed in the *B P* and *B P C* It is perhaps unfortunate—yet unavoidable—that most of the text was compiled with reference to the 1953 *B P* and 1955 *Addendum*, but a section on the changes brought about by the *B P 1958* is included at the beginning of the book It is pleasing to note that the abstracts of original papers, which are such a feature of " Martindale ", are now more critically selected, and this also applies to the therapeutic index, which no longer includes many references of historical interest only The special section on antibiotics introduced in the last edition has been expanded, and there is a valuable new section on radioactive isotopes

The text is as up to date as can be, and the editors and their collaborators are to be congratulated on a large task ably fulfilled

Atlas of Systematic Human Anatomy

Vol III GERHARD WOLF-HEIDEGGER, M D , PH D , professor of anatomy and prosector at the Anatomical Institute of the University of Basle Edinburgh and London E & S Livingstone 1957 Pp 167 55*s*

THOSE who appreciated the excellence of the first volume of Professor Wolf-Heidegger's atlas will not be disappointed in the new one, which illustrates the nervous, vascular, and lymphatic systems

Foreword and preface are in English, the section headings and title captions are in German, which is no real disadvantage to those who do not read German since the reading matter is almost entirely distributed in labels explaining the figures, which are couched in Latin No doubt some readers will be able to translate these terms into English anatomical vernacular with ease, but Prof G A G Mitchell's assumption, in the foreword, that " Latin terms are understood and employed by the majority of medical men " is overoptimistic There has been a big decline in the Latinity of medicine in the past decade or two, and it is doubtful whether students or graduates who cannot distinguish " ilium " from " ileum ", or appreciate philologically the desirability of " dorsal ", will be able to disentangle the nominatives and genitives of " confluens sinuum " or " R radicularis r spinalis a vertebralis " The section on the brain is excellent, and the draughtsmanship of the figures illustrating vessels and lymphatics is of the highest order, though many of them seem overburdened with details and labels

Just how useful are such atlases, however excellent in execution? Most professional anatomists would be at once attracted by this volume, and perhaps it should be in their departments But such atlases are too expensive for students or graduates preparing for higher qualifications, and anyway both would be better advised, like their clinical elders, to learn or revise by direct experience of living or cadaveric structure The draughtsmanship, the scholarship, the printing, are, as in some other atlases, superb, but is the effort justified?

Forensic Medicine (London Edward Arnold 1958 Pp 340 30*s*)—The medical student usually prefers a short textbook, and here he is lucky, for Dr Keith Simpson's is not only short but one of the most readable and informative of all books designed for medical students We have no hesitation in recommending it Many of the changes in the new edition have been made necessary by new laws and regulations or recently discovered drugs for which " the doctor must be on the *qui vive*—or rather *qui mort* " There are several new illustrations of good quality, but many of the familiar ones remain

Recent Advances in Obstetrics and Gynæcology (9th ed London J & A Churchill 1958 Pp 348 38*s*)—A new edition of Mr Aleck Bourne and Mr Leslie Williams' book appears every five years or so, and each is probably more valuable and popular than its predecessors The authors have by now, so to speak, got into their stride They try not to record indiscriminately all the latest discoveries, but rather to present a summary, and accompanying criticism, of consolidated advances They succeed admirably The new volume includes chapters on acute renal failure, anæmia in pregnancy (by L Steingold), coagulation defects, and intravascular thrombosis, and all are very good Purely clinical are those dealing with the present knowledge of uterine cancer and that entitled Changing Trends in Obstetrics, in which is to be found a faint hint of things to come Under antenatal care are considered anæmia, diabetes, abnormal weight gain, and the dangers of radiology—no mention of the mechanistic troubles that occupied so prominent a place in the past Perhaps in a future edition the whole chapter on antenatal care will be concerned with the importance of securing and maintaining the health of the pregnant woman The authors are so broad-minded as to present all sides of any debatable subject and so experienced as to be dogmatic when dogma is desirable The book is well illustrated and so delightfully written that the authors must plainly have enjoyed their task This excellent production is probably the best of the series

THE LANCET
LONDON 19 APRIL 1958

Influenza 1889 and 1957

It is nearly a year since the influenza epidemic which began in China reached Hong Kong and Singapore From the beginning this epidemic aroused more than ordinary public interest, because of the predictions (accurate in the event) that the Asian virus would spread throughout the world, and because of the rush to prepare vaccine with the new virus in advance of the epidemic wave But there was another reason for public interest and for some disquiet In the minds of many people epidemic influenza is forever associated with the pandemic of 1918–19, when influenza is estimated to have caused nearly 20 million deaths, and echoes of this were awakened by a series of most unusual laboratory findings

Very early in the epidemic Meyer et al[1] showed that sera taken from people before the epidemic reached the U S A were virtually devoid of antibodies to the Asian virus This finding was an important factor in predicting a high incidence of influenza in the autumn of 1957, and it also allowed the conclusion that viruses like the Asian virus were newcomers to the population Shortly afterwards, however, Mulder[2] reported briefly that some of the people in Holland aged 80–90 had small amounts of antibody to the Asian virus Since antibody was known to be rare or absent in younger people, Mulder suggested that the antibody in these old people might have resulted from infection during their childhood with a virus closely related to the Asian virus These childhood infections could have corresponded in time with the world-wide influenza epidemic of 1889, which suggests a most interesting hypothesis —that after the 1889 epidemic the virus remained dormant, possibly in an animal reservoir, until it reappeared in 1957 This week we publish three important papers describing evidence for and against this hypothesis The arguments are to some extent concerned with technical laboratory findings, but this is not just an academic problem If Mulder's hypothesis is correct we have to ask ourselves what has happened to the virus of the 1918–19 pandemic Will it, too, reappear, and if so will it be as virulent as before?

Professor Mulder and Dr Masurel (p 810) describe the laboratory findings concerning antibodies to the Asian virus and outline the hypothesis concerning the relation to the 1889 epidemic As a first step sera were collected from people of different ages in Holland before signs of epidemic spread of the virus had appeared, and through the World Health Organisation other laboratories were asked to collaborate in this investigation The sera were examined individually for antibody to Asian virus by the hæmagglutination-inhibition test, the sera being pre-treated with a filtrate of *Vibrio choleræ* to remove normal inhibitors of agglutination Positive hæmagglutination-inhibition titres were found in 52 of 1256 sera examined The proportion of positive titres increased with age, being in the range 1–2% in the 30–69 age-group, 5% in the 70–79 group, and 22% in the 80–89 group The same sera showed antibody by an independent test (the mouse-protection test), and there is little doubt that both tests were measuring true antibody The results of complement-fixation tests with the same sera make it clear that the antibody had not resulted from recent infection with Asian viruses The problem then is what is the significance of the antibody and of its age-distribution? Mulder and Masurel conclude that the human race was in contact with the dominant hæmagglutinating antigen of the Asian virus in the last quarter of the 19th century, and that the 1957 epidemic probably represents a repetition of the 1889 epidemic We are reminded that the 1889 epidemic probably originated in Central Asia and perhaps in China Their conclusion is based, however, on the age-distribution of the antibody and on the evidence of Davenport et al[3] that, generally speaking, the age-distribution of the serum antibodies to different antigenic varieties of influenza virus reflects the prevailing viruses during the childhood of the people of the different age-groups Thus Mulder and Masurel draw an analogy between antibodies to the Asian and swine influenza viruses, there is good evidence that the latter were prevalent at the time of the 1918–19 epidemic[3-5] The conclusions of Mulder and Masurel are supported by Davenport,[6] who found that in Michigan, U S A, antibody detectable by complement-fixation with Asian-virus antigen was not present in persons below the age of 30, but was usually present at low levels in those over 30

The other side of the argument is set out by Dr Clarke and her colleagues (p 814) They found that of 154 sera collected in England before July, 1957, only 6 gave hæmagglutination-inhibiting antibody to the Asian virus, these 6 sera were from persons of various ages, and only 1 of 19 persons aged 80 or more showed antibody Sera collected in 1955 and pooled according to age in 2-year age-groups, between the ages of 2 and 78, were uniformly negative for Asian-virus antibody This was in striking contrast to the postepidemic experience 44% of 637 sera taken last November had antibody—a remarkable tribute to the powers of spread of the virus in this country The findings of Clarke et al do not support the idea that Asian antibody in pre-epidemic sera was present in any particular age-group In addition, Clarke et al examined sera from 168 young people, mostly aged 18–25, who were vaccinated in 1955 and 1956 with vaccine which did not contain Asian virus When the same sera, which had been kept stored, were subsequently tested 5% were found to have had a rise in antibody to the Asian virus Essentially the same finding was noted by Mulder and Masurel, who report that of 323 people of various ages vaccinated in 1956 and early 1957 9% subsequently had antibody to the Asian virus in their sera The only obvious explanation is that the Asian virus is not so completely unrelated to previous influenza viruses as is suggested by direct cross-testing with animal sera in the hæmagglutination-inhibition test, and this conclusion is strikingly confirmed in the paper by Dr Henle and his colleagues (p 818) They found that by means of a complement-fixation test which they have recently developed, and which uses the V (or viral-specific) antigen extracted from the virus, it was possible to demonstrate antigenic relationships between the Asian virus and three viruses isolated in 1933, 1951, and 1953 This cryptic relationship had not been suspected from the results of direct hæmagglutination-inhibition tests, and it may explain why antibody to Asian virus can develop in young people vaccinated with influenza viruses apparently quite different from the Asian virus

How then are we to account for the fact that before the Asian epidemic those with Asian antibody were concentrated in the older age-groups? A hint is given in the report by Dr Holland and his colleagues (p 820) They found that Asian virus given as a single dose of vaccine induced a very poor antibody response By contrast, the same dose of vaccine given to people previously infected with Asian virus or to people who had previously been given one dose of Asian-virus vaccine led to a good antibody response By extending this finding we could postulate that repeated infection of people over many years with viruses containing a cryptic "Asian" antigen could have induced Asian antibody, whereas single infections would not have done so, and it is among older people that repeated infections of this kind would be expected to occur This hypothesis is strengthened by the finding of Henle et al that in guineapigs given repeated intranasal inoculations of different viruses a very specific antibody response gradually broadened to embrace more and more viruses, including the Asian virus, which had not been included among the viruses inoculated

This reasoning is in line with that of Hilleman et al,[7] who have studied the distribution of antibody to Asian virus in pre-epidemic sera among different age-groups in the population near Washington They were concerned with one technical aspect of the hæmagglutination-inhibition test—that treating the sera with *Vibrio choleræ* filtrate may destroy traces of antibody along with normal inhibitors of agglutination When they used a strain of virus which was not sensitive to these normal inhibitors, and thus were able to avoid using *Vibrio choleræ* filtrate, they found that the age-distribution of Asian-virus antibody was not sharply confined to older people, there were low antibody levels in people aged 20–40, and the levels rose gradually to a maximum in people aged 50–59 and remained the same thereafter This technical factor may explain the differences in age-distribution found by different investigators But Hilleman et al also show, as did Henle et al by an independent technique, that the distribution of antibody to older strains is not confined to people who were alive at the time when these strains were prevalent The same finding was noted in the sera of Nigerians by Isaacs,[8] who concluded that antibody to an influenza virus could not be taken as evidence of infection with that particular virus, but might result from infection with strains with which it shared minor antigens Thus it seems that the antibody spectrum in the population does not sharply reflect previous experience with influenza viruses, the mirror images are blurred, and we should beware of overestimating our powers of focusing them

There is a practical aspect of this controversy in connection with influenza vaccines Davenport,[6] who has accepted the idea that the 1957 virus is very similar to the 1889 virus, takes this conclusion as evidence for his belief that influenza viruses contain a finite number of antigens and that the viruses of the past will reappear as immunity to them in the population gradually recedes Davenport believes that if the number of antigens in the influenza virus is relatively small it will be possible to prepare a polyvalent vaccine which would protect against all the possible antigenic forms that the influenza viruses could assume Alternatively, if influenza viruses can mutate freely there is little to be gained by this approach to influenza vaccination, and vaccines should incorporate up-to-date viruses and thus at least take account of the most recent major antigenic change of the virus As with most theoretical arguments, theories are of little account compared with facts The only way to settle this controversy is to compare the protective power of polyvalent vaccines made from older strains with vaccine made from a more up-to-date strain This was in fact done in the recent epidemic In this country the Medical Research Council's Committee on Influenza Vaccine Trials[9] found in a carefully controlled trial that a polyvalent vaccine containing three older influenza-A viruses gave no protection, whereas a monovalent vaccine containing the Asian virus gave approximately 67% protection In a similar type of trial at Great Lakes Naval Training Centre in the U S A, a polyvalent vaccine without Asian virus is reported to have caused slight protection, estimated as 45%, which was less than that found with adequate doses of monovalent Asian vaccine[10] Experience in these trials and in previous ones in 1947–48 seems to warrant the conclusion that when a major antigenic change in the influenza virus has taken place vaccines made with older strains are unlikely to give a useful degree of protection, whereas vaccines made with the epidemic virus can give reasonable (although by no means complete) protection On the other hand, when slight antigenic changes in the virus take place there is little to be gained by using the most up-to-date virus, and the use of recent and related viruses should be just as effective

As to the whereabouts of the 1918–19 virus and whether something similar to the pandemic of that time will ever recur, we are as much in the dark as before But one thing is clear—there is less excuse than ever for relaxing our watch on the influenza viruses

Cancer of the Large Bowel

With scrupulous attention to history and examination the diagnosis of cancer in the large bowel should not often be missed From an analysis of 1023 cases in the U S A , Postlethwait et al [1] have found abdominal pain and change in bowel habit or character of the stool to be the predominant symptoms, and Muir [2] reports similar findings in 714 patients in this country But there is an odd discrepancy between the two series In the American cases bleeding was the commonest symptom of rectal cancer and the second commonest of cancer elsewhere in the large bowel In the British cases bleeding was one of the main symptoms in less than 10% of patients with neoplasms in right or left colon, in 30% (fourth in order of precedence) of those with neoplasms in the sigmoid, and in 66% (second place to "bowel complaint") when the rectum was involved Perhaps cancer education has caused American patients to become more observant and less phlegmatic than the British

It is an odd paradox that investigations can sometimes put us off the diagnostic scent Many patients now present themselves with vague abdominal symptoms requiring investigation to exclude organic disease, and a negative result may wrongly be given greater weight than the evidence of symptoms or signs Ramsay [3] has drawn attention to this danger in six years at the Gordon Hospital, London, 2325 barium enemas were undertaken and 151 patients with colonic cancer were treated Of these 151, 75 had been radiographed, and a negative report had been given in 10, leading to delay in diagnosis in 7—despite sufficient clinical evidence to warrant laparotomy A history or symptom suggesting carcinoma should take priority over a normal radiographic appearance, and radiographic evidence should be allowed to outweigh clinical evidence only when X rays show positive changes

Recurrence at the suture-line after resection remains a problem [4] The mechanism is uncertain; Goligher et al [5] and Cole [6] believe that implantation of malignant cells at the time of operation is an important cause Certainly such cells do exfoliate from the lesion —a process presumably encouraged by operative manipulation Indeed Pomeranz and Garlock [7] suggest that recurrences are brought about in the wound and peritoneal cavity by exfoliated cells transported there on the surgeon's gloves Goligher et al , who were concerned with sphincter-saving resections for growths of rectum or rectosigmoid, thought that possibly only half of 23 recurrences could be explained on the implantation hypothesis, others being due to fresh lesions or incomplete removal of the original one Likewise of 108 recurrences seen at the Mayo Clinic after anterior resection, 12 were attributable to incomplete excision, and 7 to further neoplastic degeneration in a potentially malignant mucosa [8] In the rest (less 10 cases in which the original specimen could not be examined) there was no clear explanation other than by the implantation theory, and Lofgren et al [8] observe that this would explain why recurrence at the suture-line is independent of lymph-gland metastasis and takes place soon after operation The Mayo Clinic series were compared with a control group of 102 patients who survived anterior resection for five years, no significant features could be found on examination of the specimens from the two groups Cole and Southwick [9] have found that malignant cells can be detected growing inside the veins at the tumour site or close by, and that such cells appear in a venous perfusate of the lesion, thus this type of recurrence may be caused as much by local venous invasion as by the intramural and pericolic retrograde lymphatic spread suggested by Beal and Cornell,[10] in whose series lymph-node involvement and invasion of the entire colonic wall was common at the primary lesion—in contrast to experience at the Mayo Clinic [8] In addition to the technical precautions suggested by Cole to minimise the possibility of implantation (namely, isolating the growth with tape ligatures placed round the bowel) and by Pomeranz and Garlock (who cover the surface of the lesion), Beal and Cornell suggest that the limits of resection should be extended

In 19 of Beal and Cornell's 21 cases of recurrence after resection in 140 patients, the original growth was on the left side Such a preponderance of recurrence, not noted in the other series, could be explained by the fact that this is the common site for polyps, the inference then being either that recurrence is due to small polyps at the suture-line not observed at operation (in 1 postoperative death a residual papilloma was found adjacent to the anastomosis) or that polyps developing in the natural course of events cause the primary lesion and develop again in the predisposed mucosa on either side of the anastomosis But opinions are divided as to whether small papillomas are sinister, Grinnell [11] maintains that they are not if the lesion is less than 1 cm in diameter, while Weingarten and Turell report malignancy in polyps as small as 3 mm [12] Figiel et al ,[13] who can demonstrate small lesions of the colon with greater ease by their high-voltage " spot-compression " technique, suggest that small asymptomatic polyps beyond the range of the sigmoidoscope do not require extirpation provided the patient is kept under surveillance This raises the important issue whether all colonic polyps—adenomatous or papillomatous, large or small, on the right side or the left—should be regarded as premalignant and treated accordingly Correlation between the incidence of polyps and that of cancer is not immediately obvious, in 50,000 routine proctosigmoidoscopic examinations Portes and Majarakis[14] found polyps in 7 9%, cancer in 0 685% This question is important in management, for already Lillehei and Wangensteen[15] have advocated total or subtotal colectomy for cancer distal to the hepatic flexure and similarly for right-side lesions provided no more than 20 cm of ileum has to be removed (if more is taken, then the sigmoid may need to be retained in order to avoid diarrhœa following ileoproctostomy) Further support for this approach has come from Teicher and Abrahams[16], but Grinnell,[11] after studying 1335 cases with adenomas and papillomas, found that only 1 in 67 might have benefited from such major procedures, and 8 out of 66 with multiple cancers would have similarly benefited—this representing 0 73% of 1083 cancer resections during the period under review Wakeley and Graves[17] remark that simple removal of a papilloma that is proved histologically to be carcinomatous is sometimes not followed by recurrence Turnbull,[18] who reports on 86 patients treated for carcinoma in polyps of the colon and rectum, considers that no hard-and-fast rules can be set forth for their treatment

Cerebral Palsy

Cerebral palsy is a topic that bristles with difficulties, and one of the sharpest bristles is the nosological The term includes a variety of lesions of the brain, each with various origins and various clinical manifestations It has some merit in that patients with cerebral palsy (which may be defined as a congenital motor deficiency that is not progressive) tend to have certain needs in common, but it has drawbacks too, in that the needs of children with cerebral palsy, so defined, differ from case to case, and overlap those of some children with acquired lesions (e g, from encephalitis early in life) who present a similar clinical picture Not only does the nature and severity of the motor defect vary widely, but some children have also severe mental defect, others little or none, some have fits, some athetosis, others neither, about 20% have severe hearing defects, which may not be detected until audiometry is done[19] and may be misdiagnosed as mental defect, and some (as many as 50%) have impaired sensation, the importance of which is just being recognised—it is of little use to train a child to use a limb that he cannot feel[20] Moreover, family circumstances (the income and intelligence of the parents, the presence of siblings, and the geographical situation of the home) partly determine the needs of individual patients "Go in fear of the abstract" was Ezra Pound's advice to poets "go in fear of the general" might be a good motto for doctors, especially where the particular circumstances and needs range as widely as they do in cerebral palsy

There is no cure for cerebral palsy, the damage to the brain, or failure in its development, cannot be made good But much can be done to help muscle development and coordination, by making the most of the power that remains, and perhaps by bringing to the surface dormant reflex patterns that are not used by people with undamaged brains[21] Drug treatment may help K H Sparup, in a letter,[22] and Alan Moncrieff, in a lecture to the British Council for the Welfare of Spastics,[20] have referred to the varying results when primidone is given for athetosis associated with cerebral palsy, and meprobamate for spasticity or athetosis There is also a place for operation in some cases hemispherectomy has abolished fits and temper tantrums without making the paralysis worse[23 24] There is some hope that athetosis may be improved by a method, mentioned by Professor Moncrieff, of injecting alcohol, with or without celloidin, into the corpus striatum, but such techniques are still being developed and tested, and though it is of great value to remove the handicap that athetosis or epilepsy adds to the paralysis, the chief disability remains

It is very important, then, that the child with cerebral palsy should have the best possible treatment for his motor defect, this treatment is educative, and to be effective must begin soon The aim, at least in some centres, is to make as many as possible of these children capable of going to normal schools at school age,[25] which means that the diagnosis must be reached as early as possible—and that, once this has been done, treatment must not be delayed At present the delay is often too long Dr Lawson, in his account (p 840) of the cerebral-palsy unit at Queen Mary's Hospital, Carshalton, says that only a tenth of the patients were referred in the first eighteen months of life, and a third were over the age of 5 years, while Ingram[26] found that only 4 of 79 spastic children were correctly diagnosed in the first year Early diagnosis is far from easy Moncrieff mentions such slight signs as "a little undue flabbiness, a rather suspicious rolling of the head there is often a suspicious sort of rigidity present", and he refers to the spastic tone of the spastic child, contrasted with the plastic tone of the athetoid child—"there is a feeling about the movements which those who work with these children know about, which, as we have found, is difficult to explain to other people" Those in the best position to detect cerebral palsy early are child-welfare workers and the family doctors who take a special interest in babies, who are most likely to detect slight differences from the normal Ideally all babies should be examined periodically by a doctor, and such examination is definitely necessary wherever there has been any complication of pregnancy, labour, or the neonatal

period. But making a firm diagnosis requires a good deal of experience of cerebral palsy: indeed, Dr Lawson holds that about 50 new cases must be seen every year if facility is to be acquired in diagnosis and treatment. The work of such a special diagnostic unit includes estimation of intelligence as well as of motor function, in the children with cerebral palsy the prognosis and treatment depend in part on the mental ability. Those with normal intelligence can often learn to use their motor system in such a way that no deformity develops.[27] It is of course far from easy to estimate intelligence in infants, but some useful tests are given by Mrs Collis.[28]

When the diagnosis has been made, treatment must begin at once, to prevent abnormalities of function and structure. But in each case the physician must decide, not only the treatment given, but also who is to give it, and where. In the article we published last week Dr Ellis estimates the part that individuals and voluntary agencies must play, and the responsibility of society in providing the range of institutions needed. Surveying the provision made for 133 cerebral-palsy children of school age in three local-authority areas, he contrasts it with the provision he regards as desirable. He would have fewer patients attending normal schools because many had "specific learning difficulties or were so backward that they needed more individual help than their teachers could afford to give them." He thinks that a much larger proportion should attend schools for the educationally subnormal—of which there is a general shortage. About a third, he believes, should be in schools or occupation centres specially established for children with cerebral palsy. Dr Lawson suggests that children with cerebral palsy should go to the type of school most suitable in each individual case, but be grouped in certain schools in a wide area: this would ease cooperation between the schools and the cerebral-palsy service. Both Dr Lawson and Dr Ellis emphasise the importance of parents being instructed and taking part constantly in the treatment when the child is living at home.

Even in a closely packed community such as ours there are geographical difficulties. At Dr Lawson's clinic, 40% of the patients are referred from places more than 50 miles away, and in such cases little can be done besides making a diagnosis, unless patients are admitted, which is undesirable for more than a very few. The answer is not to set up such clinics everywhere, because (Dr Lawson estimates) a catchment area with a population of 2 million is needed to provide the 50 new cases a year that the staff must see to get enough experience. Such clinics should probably be at hospitals, because for complete diagnosis audiometry, electroencephalography, and other aids are sometimes wanted. There is a need for perhaps one or two diagnostic clinics in each great city or conurbation, but (apart from exceptional cases) they need treat only the children who live on their doorstep. Most of the rest could probably be treated adequately in the various kinds of institution specified by Dr Ellis, with guidance by the special diagnostic centres, which could serve both as examples of the best in treatment and as places where new methods are explored. And in our concern for children, we must not forget the needs of the increasing numbers who survive to adult life with cerebral palsy. On p. 842 Dr Palmer reminds us of their special problems and shows what can be achieved.

Finally, Professor Moncrieff wonders whether a child with cerebral palsy should ever go to a normal school. Among the often neglected disabilities to which he draws attention, besides deafness and sensory defect, is the emotional warping. He quotes R. K. Byers, of Boston, as saying that the yardstick of successful treatment now is not motor development but emotional adjustment. The child with cerebral palsy is not a source of joy to his parents, and is surrounded by anxiety. More interest than hitherto should be given to supplying emotional and sensory experience, instead of concentrating only on motor defects. The child with cerebral palsy differs much from a child of the same intellect and motor disability who lived a normal life for a few years before having, say, poliomyelitis, and the same type of school may not be suitable for both. "It is something to be worked out." A spastic child may be distracted, bewildered, and upset among normal children, and may even make better progress in isolation.

It is clear that, on many topics, those who have done most work on cerebral palsy are not in agreement. We need more exact knowledge of the results of various methods of management, and investigations into the causes and prevention of cerebral palsy, not so much now by retrospective inquiry as by prospective and physiological investigations. The therapeutic work is as important as it is valiant, and will long be needed, but there is a limit to what even the most devoted and skilful therapist can do, and we must find ways of preventing the disability more often. The two national societies have done a valuable service in calling attention to cerebral palsy, stimulating research, and coordinating activity. So far as the medical profession is concerned, this is being continued by the National Spastics Society's issue of a new quarterly journal, the *Cerebral Palsy Bulletin*,[29] edited by Dr E. Clayton-Jones, which hopes to "stimulate interest in the scientific and clinical aspects of the various forms of cerebral palsy." This issue contains a brief biography of Little (which recalls that his first account of "Little's disease" appeared in this journal[30]) and a reprint of his paper read to the Obstetrical Society of London in 1861, based on 200 cases he had seen. The next issue will contain abstracts from and comments on recent publications.

The two national societies may be relied on to go on with their excellent work, but we must agree with Professor Moncrieff that it is not in the best interests of the patients (or of those whose admirable voluntary efforts are duplicated) that there should be two societies, and we hope that means can be found for their fusion.

Annotations

USE AND TOXICITY OF SULPHONAMIDES

SULPHONAMIDES have been in use for over twenty years Starting with the original 'Prontosil Rubrum', the aim has been to find derivatives which are more potent in antibacterial activity and less toxic to man It is an advantage if the frequency of administration can be reduced, so that disturbance of the patient at night can be avoided without the blood-level falling below that required for therapeutic effect The sulphonamides now in common use, either singly or in various mixtures, for the treatment of systemic infections include sulphathiazole, sulphadiazine, sulphamerazine, and sulphadimidine

It is doubtful whether, as regards antibacterial activity, there is much difference between these four compounds The choice should accordingly be based on toxicity, absorption, persistence of effective concentration in the blood, and frequency and convenience of administration In these respects the four differ considerably Sulphathiazole is undoubtedly the most toxic, being especially liable to cause rashes and drug fever It and its acetyl derivative are relatively insoluble in acid urine, it is rapidly excreted, and frequent administration is required to maintain an adequate blood concentration Sulphathiazole appears in the *British National Formulary, 1957* but is omitted from the *British Pharmacopœia, 1958* Sulphadiazine and sulphamerazine are less liable to cause generalised toxic effects, but they and their acetyl derivatives are relatively insoluble in urine Dr Arneil, in his article this week, draws attention again to the particular danger of sulphamerazine causing hæmaturia in children Sulphadimidine is safer since it is relatively soluble, even in an acid urine, in both its free and acetylated form [1]

The risk of injuring the kidneys with sulphathiazole, sulphadiazine, and sulphamerazine may be reduced by ensuring a high fluid intake to increase the volume of urine and by making the urine alkaline Unfortunately, these precautions are troublesome and sometimes neglected, and often insufficient alkali is given Recognising these difficulties, Lehr [2] introduced the principle of sulphonamide mixtures to reduce the liability to crystal formation in the urine The tendency to crystal deposition varies with the concentration of each individual sulphonamide, and thus is considerably less in a mixture of several compounds, but the therapeutic effect is that of the total concentration The *National Formulary* describes trisulphonamide tablets for adults and a mixture for infants containing sulphathiazole, sulphadiazine, and sulphamerazine

The question arises whether there is still any place for these more toxic sulphonamides, even in mixtures, for many antibiotics, on the whole less dangerous than the sulphonamides, have been introduced—including phenoxymethylpenicillin, which can be given by mouth There is probably no sufficient reason for retaining the relatively toxic sulphathiazole in sulphonamide mixtures [2] The closely related compounds—sulphadiazine, sulphamerazine, and sulphadimidine—differ little from sulphathiazole in their absorption, their penetration into the cerebrospinal fluid, and the ease with which a therapeutic blood-level is maintained Sulphadimidine shows slightly greater plasma binding and conjugation than the other two compounds,[3] but it is doubtful whether this substantially affects therapeutic efficacy Sulphadimidine is much less likely to cause renal damage, and is therefore preferable certainly to any single component of the official mixtures and probably to the mixtures themselves The practising doctor may be well advised to avoid entirely the more hazardous preparations—sulphathiazole, sulphadiazine, and sulphamerazine—either singly or in combination with each other or with antibiotics This applies especially to sulphamerazine for children, in whom the risk of hæmaturia is particularly great If administration of sulphadimidine is not followed by adequate response, a change should be made to a suitable antibiotic and not to another sulphonamide or a mixture of sulphonamides On the other hand sulphadimidine (and possibly newer equally non-toxic sulphonamides which have not been so fully evaluated) still have a definite place in therapeutics They are especially valuable in meningococcal septicæmia and meningitis, and in certain urinary-tract infections But the use of even these sulphonamides is not without risk, and attention must always be paid to dosage, renal function, and fluid intake

THIRST

THIRST—the uneasy or painful sensation caused by want of drink, as the Oxford Dictionary defines it—being subjective is difficult to investigate But if it can be assumed that in laboratory animals drinking implies a state analogous to thirst, then a dry mouth is not the whole story [4] and a "drinking-centre" exists Pure water-deficiency results in thirst, but hyperosmolarity is unlikely to play a large part because the hyperosmolarity associated with other disturbances—for example, increased blood-urea—does not increase thirst unless there is an accompanying diuresis A change in the distribution of body-fluid may be important Thus, salt depletion can give rise to a sensation of thirst that is not slaked by pure water but can be relieved by small amounts of hypertonic saline solution [5] Salt depletion causes the extracellular-fluid volume to contract, and it seems that shrinkage of this volume results in the urge to drink Removal of a large volume of extracellular fluid, such as isotonic ascitic fluid, also leads to thirst the paracentesis cannot affect the osmotic pressure of the body-fluid, but it does affect its total volume and compartmental distribution Thirst has been noted [6] as a symptom of impending diarrhœa, because, it is believed, of the reduction of volume of extracellular fluid following sequestration of isotonic fluid in the lumen of the intestine It seems, therefore, that although a rise in the osmotic pressure of the body-fluids without change in volume *may* lead to thirst, changes of the volumes in fluid compartments *always* lead to thirst

Most of the work on the neural integration of thirst has been done in goats Polydipsia results from hypothalamic stimulation, either by local injection of 2% sodium chloride or by electrical stimulation [7] Direct evidence of a "drinking-centre" in man is difficult to obtain, though rare cases are described in which diabetes insipidus and anterior-pituitary insufficiency together allow a greater loss than intake of fluid, leading to hyperosmolarity of body-fluids The effect of impulses from peripheral nerves is evident in the influence on the drinking response of a dry mouth and of gastric distension with a balloon,[8] and in the pharyngeal "metering" of fluid intake in dogs with œsophageal fistula[9] The evidence so far has led to the postulate[10] that the hypothalamus contains receptors which regulate water intake as well as output, and presumably receptors concerned with intake are stimulated, partly by changes in the volume of the fluid compartments, and partly by afferent impulses from the gastrointestinal tract.

CERVICOTHORACIC GANGLIONECTOMY

THE results of cervicothoracic ganglionectomy in the treatment of arterial lesions reflect the selection of patients submitted to operation rather than the particular technique of sympathetic interruption Raynaud's disease as defined by Allen and Brown[11] must have been present bilaterally for at least two years, the colour changes occur on exposure to emotion or cold, and gangrene or any primary associated disease such as acrosclerosis are absent Gifford et al[12] review 70 such patients, all women and mostly below 40 years of age, who some years ago were submitted to resection of the stellate ganglion, and often the second thoracic Their results mirror those already published less than half the patients definitely benefited, and in some the disability was actually enhanced Gifford et al agree that the results in secondary Raynaud's phenomenon, such as may accompany acrosclerosis, are the worst, while those in the lower limb are better than those in the upper limb Their data do not reveal any way by which the results of sympathectomy in the upper extremities can be predicted in advance, except that good results were obtained more often when complications of Raynaud's disease, such as nutritional changes, were not present before operation Before deciding to operate it is important to exclude the many other conditions which may be associated with digital colour changes—particularly the so-called collagen diseases Most patients with these other disorders are in no way helped by sympathectomy, and in some the primary disease may be aggravated Raynaud's phenomenon due to a local fault, such as sometimes follows prolonged use of a vibratory tool, is not benefited; but where the sympathetic impulses play an essential part in the causation of symptoms interruption of the nervous control will be followed by great relief What is much needed now is a simple clinical test to establish the relative importance of the various factors which contribute to the Raynaud phenomenon

IMMUNOLOGY

IN view of the importance of immunological phenomena in medical and veterinary practice as well as in the wider fields of biology, it is surprising that hitherto Britain has had no scientific society devoted mainly to advancing our knowledge of immunity In many countries—notably the U S.A and Germany—active immunological societies with specialised journals of international repute have existed for many years In recent years the scope of immunology has increased enormously, and it now encompasses the increasingly important subjects of allergy, auto-antibodies and their possible role in the pathogenesis of many common diseases, and homograft immunity and acquired tolerance In addition, it has a large stake in genetics, mainly by virtue of its importance in the realm of blood-groups and blood-group substances, as well as lesser but none the less important interests in the pathogenesis of tumours On a slightly less biological level it claims many devotees in the fields of pure chemistry and physics This growth pressure led to the formation, in the autumn of 1956, of the British Society for Immunology The necessity for a journal of its own was immediately appreciated by the new society, and within fourteen months of the inaugural meeting there has appeared the first issue of *Immunology*,[1] the society's official journal, under the editorship of Prof J R Marrack.

This issue confirms the greatly widened range of the subject Thus the opening paper, by P B Medawar and P S Russell, on adrenal homografts in mice with special reference to immunological adrenalectomy, deals with how to overcome the immune reaction that at present vitiates the most skilful attempts to transplant tissues from one individual to another The paper by B Cruickshank and A. R Currie on the localisation of tissue antigens by the fluorescent antibody technique is a further example of the extension of this exciting immunological method[2] into other fields of physiology and pathology Other contributors show well the present physical trend in immunology, and the more chemical approach is represented by a study of the components of mycobacteria that influence antibody production

A CHAIR OF PÆDIATRIC SURGERY

THE news of the appointment of Mr A W Wilkinson as the first professor of pædiatric surgery at the Institute of Child Health in the University of London (see p 861) is of exceptional interest, for there is only one similar chair in the world—at Boston, Massachusetts It is fitting that such a chair should be established at the Institute, for the associated Hospital for Sick Children, Great Ormond Street, has been the scene of pioneer work on surgery in the young, which the new academic unit will be able to consolidate This development has been made possible by a gift of £80,000 from the Nuffield Foundation, to mark Lord Nuffield's 80th birthday It was at the Institute that in 1945 the first Nuffield chair—that of child health—was created

THE BUDGET

IN the past year the level of unemployment has risen from 1 7% to 2 0% Mr Heathcoat Amory, the Chancellor of the Exchequer, when he introduced his first Budget last Tuesday, would no doubt have liked to stimulate demand by sweeping cuts in taxation But Britain's falling share of world trade, and the continuing need to strengthen sterling, prevented such a move, and his main tax concession consists in curtailing the rate of purchase-tax on goods subject to this tax at the highest rates The limits of income-tax exemption for the elderly are to be slightly raised, and the aged relief limit is to go up from £700 to £800 These concessions, though they are not large and affect only some of the elderly, give welcome recognition to the difficulties of this section of the population in making ends meet

A CEREBRAL-PALSY SERVICE FOR CHILDREN

DAVID LAWSON
M.D. Cantab., M.R.C.P.
PHYSICIAN-SUPERINTENDENT, CONSULTANT PÆDIATRICIAN, AND DIRECTOR OF CEREBRAL PALSY UNIT, QUEEN MARY'S HOSPITAL FOR CHILDREN, CARSHALTON

THE cerebral-palsy unit at Queen Mary's Hospital for Children, Carshalton, has been running continuously since 1943, and the parental-advice clinic since 1945. In August, 1957, 157 patients were in the care of this service: 17 were in the residential unit and 140 were attending the advice clinics with their parents. Of these 140, 59 had attended for up to three years, 47 for from three to six years, 27 for from six to nine years, 6 for from nine to twelve years, and 1 for thirteen years.

This article analyses the experience of the diagnostic clinic and of the new entrants to the advice-clinic service over the years 1954–56, during which time 206 cases were referred.

The principles underlying the running of this unit have been described by Collis et al. (1956), and only the structure of the service will be outlined here.

There is an inpatient unit of 20 beds, within a general children's hospital, working in close cooperation with a hospital school, and including on its staff two specially trained teachers.

New patients are seen with their parents at a diagnostic clinic where, following history-taking and examination, a decision is taken on the following questions:

1. Is this a case of cerebral palsy?
2. If it is, what type is it, and to what extent, if at all, is there evidence of a complicating mental defect?
3. Are there already incipient or established secondary deformities?

In difficult cases a decision may be delayed until after a period of observation in the inpatient unit.

The prognosis, both physical and mental, is then explained to and discussed with the parents, and the services of the advice clinic are offered to them.

They are told that the day-to-day management and guidance of their children does not need any special technical facility, and that affected children will make better and faster progress if they are looked after by their parents. The day-to-day continuity of treatment needed is such that nobody but the parent can carry it out, unless the child is to be admitted for a very long period to a heavily staffed unit, and thus separated from his home for long periods during his formative years. When parents accept this offer, advice-clinic visits are arranged at about monthly, and later at longer, intervals.

The limited purpose of what follows is to analyse the initial assessment of cases and the extent to which advice-clinic services are accepted and used, and to point to certain unresolved problems which may be of wider interest.

ANALYSIS OF CASES

Of the 206 patients referred to the clinic in 1954–56, 68 were found to have mental defect only, and the parents were given advice by the almoner or referred to the mental health authorities where appropriate. 11 children were found to have neither cerebral palsy nor mental deficiency. Most of these were normal children whose progress, though it had given cause for alarm, was considered to be within the normal range. The remaining 127 had cerebral palsy in one of its forms, with or without some mental defect. These cases fell into the following clinical categories:

Generalised spasticity	76 cases
Variable rigidity	19 cases
Athetoid cerebral palsy	3 cases
Ataxia	3 cases
Congenital hemiplegia	21 cases
Acquired hemiplegia	5 cases

Of these 127, 38 did not initially accept the services of the advice clinic for various reasons, among which geographical reasons predominated. The remaining 89 accepted the service offered, but of these 28 had ceased to attend within a few months. The reasons for this cessation were again largely geographical, but some who stopped had accepted other advice, and in some the cerebral palsy was complicated by such severe mental deficiency that institutional management elsewhere was arranged at parental request. Of the original 127 cases, therefore, only 61 (48%) effectively accepted the advice-clinic services.

This clinic acts to some extent as a reference clinic for cases over a wide area, and for those who come a long distance it is often impossible to offer more than diagnosis and initial advice. Of the 127 cases, about 40% came from the London or Surrey areas, 20% from other counties near London, and 40% from more than 50 miles away.

The services of the advice clinic are invariably offered to all who wish to come, whatever the degree of mental defect, but it is the parents of the most severely mentally affected children who most commonly fail to make consistent use of the service, because it is to them that it has least to offer.

Intelligence

Following clinical assessment, the cases are grouped into one of four intelligence levels, in terms of the probably appropriate form of education or training at school age:

1	Probably capable of receiving education at a normal school	31 (24%)
2	Requiring education in an educationally subnormal school	30 (21%)
3	Borderline of educability	18 (14%)
4	Ineducable	48 (38%)

The probable social prognoses, taking account of both mental and physical disability, were as follows:

Independent	36 (28%)
Partially dependent (that is to say, probably capable in due course of taking up limited and carefully arranged employment, but not capable of living a fully independent life)	26 (20%)
Dependent	65 (51%)

Ætiology

It is seldom possible to assign a cause with certainty in individual cases. For example, though there is a definite association between cerebral palsy and fœtal or neonatal anoxia, the extent of this anoxia is not measurable, and many infants suffer anoxia without developing cerebral palsy. The analysis of a large series, however, may well show significant associations. Among the various factors analysed in the case-histories, the following were found:

Definite clinical evidence of neonatal anoxia	40 cases (31%)
Maternal toxæmia	10 cases (8%)
Long or difficult labour	17 cases (13%)
Long-continued neonatal jaundice, including hæmolytic disease of the newborn	16 cases (13%)

Many cases of cerebral palsy could be diagnosed earlier than at present if all babies with a history of any maternal disease or complication of pregnancy, labour, or the neonatal period were followed up carefully for a year or two Even if this were done, however, a substantial proportion of cases would still be found to arise in babies without such histories Of the 121 cases of congenital cerebral palsy in our series, in 43 (36%) there was no history of any of the following antepartum hæmorrhage, anoxia, forceps delivery, maternal toxæmia, precipitate labour, long or difficult labour, long-continued neonatal jaundice, hæmolytic disease of the newborn, birth-weight under 3 pounds It is difficult to see how these cases could be picked up at the earliest opportunity, except by a careful follow-up of all babies In view of the very large numbers of babies concerned this could probably be done on a national scale only by the reference from baby clinics of all babies showing evidence of delay or abnormality of motor development. (In the case of the 68 children found to have mental defect only, 37 (55%) had no such history of abnormality)

Birthweight

Of the 109 cases in which reliable birthweights were obtained, 6 were over 9 lb , 53 between $5^1/_2$ and 9 lb , and 50 under $5^1/_2$ lb The incidence of prematurity was therefore 45%

Age at Referral

One of the most serious practical problems arises from the late age at which children are referred to the diagnostic clinic. It is extremely important that the diagnosis should be made early, so that the baby may be appropriately handled and guided in the acquisition of motor patterns, thus making the best use of his limited capacity from the start, and avoiding so far as possible secondary disorders of function and structure. Of the 127 children, only 13 (10%) were referred in the first eighteen months of life, a further 41 (32%) between the ages of 18 months and 3 years, 29 (23%) between the ages of 3 and 4 years, and 44 (34%) over the age of 5 years

Mental Defect With and Without Cerebral Palsy

To satisfy the parents of a mentally defective child that the child's life is not further complicated by a motor deficiency is a substantial and valuable part of the clinic's work. This opinion we have been able to give in 68 of the 206 cases referred to us The cases of mental defect or cerebral palsy or both constitute between them 195 of the total number of 206 cases referred to us These 195 cases have been classified to show the number of cases from each source and the proportion of these which were found to have mental defect only

Source	*No referred*	*Proportion found to have mental defect only*
Hospital service	76	24%
Local-authority medical officer	25	36%
General practitioner	42	40%
Parents	38	45%
Lay society	13	46%

ADMISSION TO RESIDENTIAL UNIT

Of the 86 patients who initially entered the service, 22 were admitted to the unit either for extended diagnosis or to get management firmly started along the right lines both for the mother and child, and a further 18 were subsequently admitted either because the child had difficulties in getting management effectively started as an out-patient, or to help the mother over a socially difficult period Of these 86 cases, therefore, a total of 40 (just over 45%) spent some time in the residential unit itself This was not a substitute for the system of parental care and guidance, but a necessary entree to it

DISCUSSION

Prompt Diagnosis

This can probably best be secured by the reference to experienced diagnostic clinics of all infants in whom there is any suspicion of abnormality or delay in motor development

Early Management

Early diagnosis is not always followed by immediate measures of management. Commonly when cerebral palsy has been correctly diagnosed in the 1st year of life the parents are told that nothing can be done until the child is 3 or 5 years of age By this time, failure to provide day-by-day guidance of the child's developing physical activity has resulted in avoidable abnormalities of function and of structure

Geographical Factors

Although this clinic operates in a fairly dense urban community, in close proximity to nearly 10 million people, 40% of the cases are referred from over 50 miles away, from which distance it is almost impossible to maintain the close contact which is needed if anything beyond diagnosis is to be offered Nevertheless it is difficult to see how the staff of a cerebral-palsy unit can acquire facility in the diagnosis and management of these cases without a diagnostic turnover of about 50 cases a year This turnover would correspond to the exclusive intake from a population of about 2 million (Collis et al. 1956)

Education

Experience shows that if the child is appropriately handled from the earliest years, so that by the time school age is reached he has at least three years of effective management behind him, he will be able to fit into the pattern of normal and special educational services provided or envisaged under the 1944 Education Act, and that the type of provision required will be decided more by his intellectual capacity than by his residual physical disability

It is vital that there should be close cooperation between doctor, teacher, and parent, but this we find difficult to achieve if the parent has not several years of guided experience behind her before school starts, and if the children attending an advice clinic are scattered among many schools The latter difficulty has led to the suggestion that special schools for cerebral-palsied children as such should be provided This view overlooks the very wide scatter of intelligence level in these children, which varies between the highest and lowest intelligences for which the education authority is responsible, but with a strong bias towards the lower levels A school for all cerebral-palsied children in the locality would, therefore, despite its small size, have to cater for a wider variation in intelligence levels than is provided for either in normal or in educationally subnormal schools

A compromise solution might be possible at least in densely populated areas The cerebral-palsied children could be educated in the type of school (normal, educationally subnormal, or physically handicapped) which would best suit them, but over a wide area they could be concentrated so far as possible in selected schools of the appropriate type, working in close conjunction with a cerebral-palsy advice service Even under these conditions great care would have to be taken that each child's education was planned according to his individual requirements rather than his verbal diagnosis This applies especially to the more gifted children, who, because of their higher intelligence and greater learning ability, will overcome their physical disability more rapidly and more completely than others and may well be able to do without any special educational provision

SUMMARY

In 1954–56, 206 cases were referred to the cerebral-palsy diagnostic and advisory service

34% of these patients were found to have mental defect only The exclusion of cerebral palsy in mentally defective children has become almost as important a part of the diagnostic-clinic service as the diagnosis of cerebral palsy itself

Of the children with cerebral palsy, about a quarter were regarded as sufficiently intelligent to receive normal education, while nearly 40% were probably ineducable

It is estimated that nearly a third should eventually be capable of leading a completely independent life in society, while *just over half will always be fully dependent*

40% of cases were referred from distances of over 50 miles The services of the advice clinics were offered in all cases of cerebral palsy, and were accepted in just over half the cases

Only 10% were referred in the first 18 months of life, and 34% were already of school age at referral

The figures confirm the ætiological importance of certain disorders or complications of pregnancy, labour, and the neonatal period in the ætiology of cerebral palsy, but in 36% of cases no such history was obtained In 45% of cases birth was premature (under $5^1/_2$ lb birthweight)

While accepting sole responsibility for the views expressed here, I wish to record a deep debt of gratitude to Mrs Eirene Collis, who has been continuously in day-to-day charge of the cerebral-palsy unit since she started it in 1943, and on the basis of whose devoted work my experience of cerebral palsy has been gained in a close cooperation over the past four years

PRESTED HALL

A RESIDENTIAL CENTRE FOR ADULT SPASTICS

K W Nicholls Palmer
T D, L M S S A, D Phys Med
CONSULTANT IN PHYSICAL MEDICINE, ST MARY'S HOSPITAL, COLCHESTER

Prested Hall is a residential centre for thirty men and women severely handicapped by infantile cerebral palsy It was opened by the National Spastics Society in January, 1955, and is leased to the society for a token rent The treatment unit was built by the society in the spacious grounds attached to the Hall This is, I believe, the only centre in the world catering for adult spastics offering residential physiotherapy, occupational therapy, and speech therapy, with an opportunity to lead a fuller life than is normally possible for a handicapped person in a home or institution

PROBLEM

Almost all the residents at Prested Hall are adults who have had no specific treatment for their condition and little or no special education In 3 years, ten were admitted mainly because their parents, owing to age and infirmity, were unable to care for them One came from a mental hospital where he had spent 30 years Twenty-five were admitted specifically for physical treatment and training The remaining eight were admitted from geriatric and chronic-sick units, where their companions were often more than twice their age With improvements in the care of young spastics, and more understanding of their problems and their possibilities, the proportion of admissions in the third group should decrease At present many of the admissions to any adult centre must be patients who have had no previous purposeful care and have been for years virtually relegated to the scrap-heap

The spastic presents an inextricable mixture of social, emotional, and physical difficulties Most of those who have been cared for at home have been grossly overprotected and have never been encouraged to do even simple things for themselves Some have been dressed and undressed daily by their mothers up to the age of 30 or 40 One was kept indoors for the greater part of her life, though quite capable of using a self-propelled wheel chair Such patients have learnt to depend on others and do not take easily to attempts to make them *work towards their own improvement* Some are frustrated because their disability restricts them, some have been robbed even of the wish to do things and are beyond frustration

For most, the first months at Prested Hall are their first attempt at living on equal terms with other people The new adjustment is not easy Initial reactions run the whole gamut from morbid shyness to aggressiveness In the first months after the centre was opened, this led to very considerable difficulties, but as time has passed a nucleus has developed of well-adjusted residents whose stability is a material aid to newcomers

On the physical side, *difficulty in locomotion* is probably the biggest problem The previously untreated patient has had to make some use of his arms and hands, but has not usually been encouraged to move about He is afraid of falling and is often handicapped by defective kinæsthetic sense in his legs and sense of balance A good deal of incentive and encouragement is needed to make him feel that the effort and concentration demanded by learning to walk is really worth while

DOCUMENTATION

Records are kept of all residents They include a family history where available, but, as one might expect with adults the history of confinement and early childhood was often unobtainable Capability charts are kept of daily living activities These are as simple as possible complicated graphs have been found impracticable and unnecessary Still photographs are taken of every resident in standard positions and are repeated yearly or after a major change in ability Ciné photographs are also taken of each resident performing standard tasks, including eating, drinking, and moving by whatever means possible The object is to record maximum capability, to study movement pattern, and to teach and encourage the patient The classification of the cases seems more difficult as more experience is obtained It appears possible to divide them only into predominantly spastic, athetoid, or ataxic types In almost all cases they are mixed Even in apparent hemiplegia, some defects are usually found on the opposite side There is also a proportion of additional abnormalities, including four cases of congenital deformity of the hip, one of spina bifida occulta, one of epilepsy, five of partial deafness, two with marked nystagmus, and four with marked short sight

METHOD

The centre is run with very few rules, and provides conditions as near to home as is possible with a community of this type. It has the advantage that the residents realise that there are other people with similar disabilities which they are striving to overcome. They improve with competition and an incentive is provided which they do not have at home.

The accommodation is divided into two-bedded and four-bedded rooms. Those with the most severe handicaps, dependent on wheel chairs, live on the ground floor. Washing and toilet facilities have been arranged for handicapped persons and include a wooden wheel chair for use with the shower. The cost is £12 a week for each resident. Most of this is met by the appropriate welfare authority. The National Assistance Board now contributes 40*s.* a week and 10*s.* a week pocket-money.

TREATMENT

Treatment in the *physiotherapy* department aims at increasing the resident's ability to perform everyday activities, including dressing and washing, progressing where possible to complete independence. The methods followed at first were compiled from the normal sequences of development on the lines on which most children are treated. This did not work well with adults, who have well-established movements, usually in a bad pattern. The method now used is to facilitate the righting and protective reflexes and balancing reactions, and to treat contractures and scoliosis. One handicap common to almost all adult spastics is the malformation of their feet. This may be lessened by well-fitting surgical boots and shoes.

The aim of treatment in the *occupational-therapy* department is to develop any latent skills, to assess ability to work through various tasks and crafts, and, as in the physiotherapy department, to create as great a degree of independence as possible. The patient must be treated as a whole. It is not only the ability to do a particular task but a willingness to do it and sufficient concentration to work for an economic period. Residents are encouraged to take part in group activities such as debating, play-reading, and puppetry. A kitchen unit, provided by a local Women's Institute helps to fulfil a desire to partake in normal household activities, which have often been denied at home. It has proved one of the most successful ways of preparing residents for future independence. It was thought that many aids and appliances would be needed in the kitchen to suit the residents' disabilities. This proved to be wrong. A work-bench, oven, and sink were provided at a height suitable for a wheel chair. A pull-out table, containing holes for mixing-basins, and two hand-grips were all the aids needed. The residents solved their own problems and it was found better to encourage them to overcome their disabilities without gadgets. There was a great need for elementary education, and lessons were started in the occupational therapy department. These lessons are now being continued as a night class through the local education authorities, aided by one of the residents who has passed three subjects of his general certificate of education.

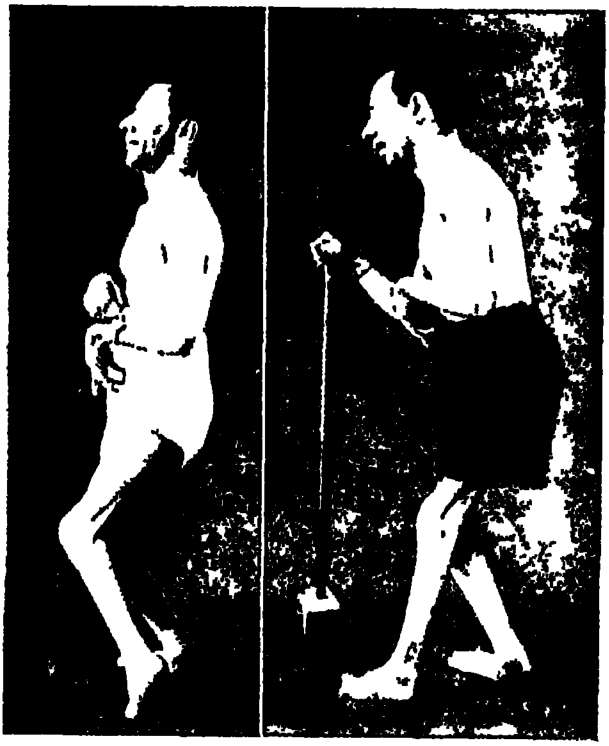
The principles which have been followed for *speech therapy* have been based on the following: general relaxation and positioning of the patient, exercises to improve control and depth of breathing, lip exercises to improve lip muscles, manipulation of the tongue, lips, and jaw to increase range of movement, stimulation of palatal movement, and mirror training to coordinate sound and movement by imitation, and to gain control of facial expression.

Eighteen patients out of thirty receive speech therapy. Only four of these can turn up the tip of the tongue on protrusion, thus sounds usually produced with the tip of the tongue on the alveolar ridge (e.g., t, d, l, n) are imperfectly formed. Inability to move the tongue to the side, occasionally only one side, is another difficulty. The tongue is often underdeveloped, and moving the middle of the tongue backwards, as in eating, is defective. Eating and drinking movements are therefore taught in the same department. In one case a dental gag has been made by a local dental surgeon for a resident who is unable to close his lips. This gag contains a 'Polythene' tube and enables him to close his mouth and suck fluids. Before he can close his mouth round this he has to stimulate his lips by stroking them. It is hoped to reduce gradually the size of the gag and finally discard it. Dribbling is fairly common. It has been improved in several cases by encouraging the patient to exercise more conscious control of the swallowing reflex.

An imperfect speech pattern may be the easiest for the spastic to acquire, but where it has failed to convey the patient's thoughts it has caused frustration. In many cases correct guidance during childhood would have produced far better speech and may well have led to better understanding.

Surgery.—Only one resident has been operated on—for flexion contractures affecting his knees.

He was 31, and before operation walked on his toes with his knees bent to about 135° (see figure, a). These knees could not be straightened under anæsthetic. After operation his knees were straight and he could place both feet flat on the ground (b). It took 8 months of daily treatment before



(*a*) (*b*)

Operation for flexion contracture of knees (*a*) before, (*b*) after

he could walk as well as before the operation. This was nearly 2 years ago, and he is now more stable than before and walking better. The delay, which might well have led to failure, was probably caused by a number of factors. The patient's pattern of walking was well established. With his feet flat on the floor there was a major change in this pattern which was very difficult for him to appreciate. This operation included a tendon release, which deprived him of part of his muscle and tendon sense, changing his reflex pattern. His drive and endurance was overestimated.

No doubt there is a place for surgery in the adult spastic, but the advantages must be very carefully considered beforehand, and endless time and patience may be needed in the after-treatment.

RECREATION

Before their arrival the residents had had almost no experience of playing games. Their reaction to ball games was that they could not and did not want to play. This attitude changed very quickly and they now enjoy modified games of tug-of-war, cricket, croquet, and football, and take part in obstacle races. The team spirit is encouraged and teams are so picked as to balance their handicaps as evenly as possible. As a result of this, big movements, involving hand and eye coordination and balance, have improved noticeably.

The residents are encouraged to manage their own affairs through their own social committee. Entertainment for those who wish to take part is provided in the lounge in the evening, and there are frequent social outings to the theatre and places of interest.

CONCLUSIONS

The treatment and management of adult spastics was approached with caution, and no dramatic results were expected. In the course of 3 years' experience the results have been encouraging. Only two out of eleven women residents could walk when they first came to Prested Hall. At the end of the first 8 months nine could walk on their own or with some mechanical aid. Of the men nine out of eighteen could walk, with or without aids, and this number was increased to eleven in the same period.

Given a chance to follow an occupation and to learn a remunerative trade, most residents have shown an ability to improve their dexterity. Two have achieved independence in a sheltered workshop. Four have improved enough to pass on to another of the society's centres for more advanced training. Five were discharged as unlikely to improve with further treatment. Two left because their local authorities withdrew their grants. One died as a result of an epileptic fit.

In seeking employment, one of the most difficult obstacles is the average employer's reluctance to take on a spastic—not necessarily because of his physical limitations, but because of his appearance. This should improve as the condition is more widely understood by the lay public. Another difficulty is the trade-union rate for the job. Most spastics are unable to work economically because they are slow, but they are quite capable of doing a good job, if they can be paid what they are worth and if they do not hold up a production team. The spastic's appearance suggests that he is accident-prone, but though there are two electric lathes, an electric drill, many sharp tools in the occupational-therapy department, and the usual kitchen ware in the kitchen, there have been no accidents so far. This suggests that spastics are not as clumsy as they often appear.

FUTURE

There is undoubtedly a need for assessment and early training of spastics before admission to industry or a specific training-centre. Unfortunately there will always be those who cannot live independently or even work economically in sheltered conditions. It will be possible to make these less dependent and more able to appreciate a fuller life by a stay at such a centre, even if they eventually have to return to their homes or some type of institution. For the future we must look to the children, and if possible prevent or reduce the incidence of spastic disease, for there is no cure. With a better understanding and better treatment of spastic children, we should see less deformity, both mental and physical. When a child is found to be spastic, the aim must be maximum capability, making the most of the remaining undamaged part of the brain.

I am grateful to Dr J D Kershaw, a member of the centre's committee, for his advice on this paper, to Mr J H Watson, the warden, and to members of the staff whose cooperation and team work have made this treatment centre possible.

AN ORAL CONTRACEPTIVE

ON April 9, at the London School of Hygiene and Tropical Medicine, Dr GREGORY PINCUS gave the second Oliver Bird lecture, on Fertility Control with Oral Medication. Sir Russell Brain, president of the Family Planning Association, took the chair.

Experiments five or six years ago, said Dr Pincus, showed that though the normal function of progesterone was to help pregnancy by ensuring implantation of the ovum, in large and appropriately timed doses it would inhibit ovulation in all species and prevent fertilisation. Since injections of progesterone were painful, and oral doses not very effective, allied compounds were sought in the hope of finding one that would be more effective by mouth. Three 19-norsteroids emerged, all especially active in inhibiting ovulation. 'Norlutin,' 'Enovid,' and 'Nilevar'—or compounds I, II, and III respectively Of these enovid was the most potent inhibitor of fertility in the rat and of ovulation in the rabbit It had some progestational effect, but less than progesterone, and some œstrogenic effect

The three compounds were tested for their effect in inhibiting ovulation in women—first in volunteers, giving one 10 mg tablet daily from the 5th to 24th days of the menstrual cycle, then in patients in a mental hospital The indices of ovulation used were (1) the peak of temperature, (2) vaginal smears, (3) endometrial biopsy, and (4) urine output of pregnanediol In the volunteers, with compound I, the mean length of the menstrual cycle was unchanged, evidence for ovulation was lacking in 76% of cycles by endometrial biopsy and in 92% by other tests, and pregnanediol excretion fell to a tenth of normal At laparotomy in 12 women, no evidence was found of recent ovulation When treatment was stopped, normal cycles were resumed, though the first was delayed The findings with compounds II and III were similar In the mental-hospital patients, there was some shortening of the cycle with compound I, but not II The plasma-free corticoids were increased or unchanged, and the plasma-bound corticoids decreased With compound II, there was diminished excretion of corticosteroids, pregnanediol, and gonadotrophin

A field trial was then begun, in cooperation with the Family Planning Association of Puerto Rico, to test the contraceptive effects of enovid Women were given tablets and told to take one daily from the 5th to the 24th day of the cycle, and were visited monthly by social workers who asked them how many tablets they had in fact taken, if they had missed any they were advised to go on till they had taken all twenty 70% of the women took the tablets daily as prescribed, in these the cycle length was normal, with a less wide range of lengths than is found in untreated women, in those who missed one to five tablets the cycle tended to be shorter or longer than normal, and in those who missed more than five the cycle tended to be longer The output of corticosteroids in the urine was decreased, the hæmoglobin and clotting-time remained the same, and the bleeding-time became a little shorter The menstrual flow seemed unchanged but there was a tendency for dysmenorrhœa to be relieved Endometrial biopsies revealed much the same picture throughout the cycle—that typical of the 19th day normally—and œdema of the stroma 14% of the women had side-reactions, such as nausea and abdominal pain, which were sometimes severe enough to cause them to abandon their tablets, but which were relieved by antacids in 90%, and by a placebo in 65%, of cases The effectiveness of the drug as a contraceptive is shown by these figures

	No of tablets missed	*No of pregnancies (per 100 woman-years)*	
Untreated		62 5 ± 1 35	
Treated			
	0	0	3 8
	1-5	9 2	
	6-19	25 9	

Dr Pincus concluded that enovid, by virtue of its action in inducing a premature luteal phase, is an effective contraceptive, and most women are happy taking it The problem in Puerto Rico is to find enough of it to satisfy the demand

The Widdicombe File

XLV. CAROLINE'S FUTURE

My dear Richard,

How *thoughtful* of you to send me your Uncle Tom's letter!* And how nice to see that he is still the same dear little boy I remember so well—perhaps a little younger, but then time does fly so, doesn't it? And what a coincidence that it should arrive just at a time when we are all so *preoccupied* with our granddaughter Carrie's future I do so vividly remember dear Noel sitting beside Jeremy and me on the beach in Capri (or was it the terrace in Naples?) and giving us the most wonderful advice about Sylvia That was Carrie's mother, of course And I wish I could remember what exactly his advice was but I know that it had something to do with her going on the stage And that really was many years before she went to America with Jim (her first) and started to collect those quaint little ottos (or are they oscars?) which now clutter up the house so badly

Well, poor Noel cannot afford to live in England any longer, so there was *nobody* to tell me what to do with Carrie until you sent me Tom's letter And I was just about to give her all the *wrong* advice! Because I *did* have misgivings about her wanting to do Medicine Such a noble profession, of course! But I *never* realised what a dreadful state it had got into and that you needed young women so badly Not until I read Tom's letter It used to be so different when I was young Why, I remember that *all* my doctor friends used to be intense about their work and I cannot remember *one* who wanted to play with first-stage rockets (whatever *they* are) instead of looking after his patients But I am sure that's all because today the poor boys are "dragged" and "pushed" and "bullied" and even "*cheated*" into the profession, instead of being allowed to stay at home No wonder they become such bad doctors But my dear Richard, you really must put poor Tom's mind at rest There is still Carrie, and some of her friends, who really *want* to do Medicine and you cannot imagine how wonderfully intense they feel about it and with so many lives entrusted to them, let us hope that they always will do (And surely there must be a *few* young men left like that!)

But then, I must confess to you, there *was* also this question of marriage that kept worrying me - Not that Carrie ever consults me or Sylvia about things like that but watching our own Dr Misgust, who comes to write up Jeremy for his sleeping-pills, I did become quite perturbed Because the poor man is always so terribly bad-tempered never a moment even to sit down, though he is really wonderfully kind and insists on sending us to the very best hospitals even when it's only a sore throat And when he did come to tea the other day I felt *so* sorry for his poor dear wife, because I am sure that she wasn't nearly so interested in cancer and yellow fever as Jeremy and I and the Vicar and Mrs Appleby and they do have tea together quite often But I see now how different it will be for Carrie After all, it *is* quite likely that she will marry a doctor and then, as Tom says, she and her husband will be able to forget about their marriage now and then and talk "shop" And when I think of all my friends and their husbands who have had *nothing* to talk about for the last thirty years, and when I have to listen to Jeremy who still talks tinned fruit (although it's five years now since he retired) every time I want to talk to him about something *interesting*, well, isn't it going to be fun for Carrie and her husband to talk the *same* "shop" to each other any time they feel like talking? But, of course, Carrie might not marry a doctor only why does Tom say that if she didn't, it would have to be a poor half-wit? Not that I think that all husbands need to be intelligent, or even bright but it is really distressing to think that there are only a few Englishmen left who are able to grasp that being a doctor one cannot *help* learning

---

XLV. CAROLINE'S FUTURE

MY DEAR RICHARD,

How *thoughtful* of you to send me your Uncle Tom's letter!* And how nice to see that he is still the same dear little boy I remember so well—perhaps a little younger, but then time does fly so, doesn't it? And what a coincidence that it should arrive just at a time when we are all so *preoccupied* with our granddaughter Carrie's future I do so vividly remember dear Noel sitting beside Jeremy and me on the beach in Capri (or was it the terrace in Naples?) and giving us the most wonderful advice about Sylvia That was Carrie's mother, of course And I wish I could remember what exactly his advice was but I know that it had something to do with her going on the stage And that really was many years before she went to America with Jim (her first) and started to collect those quaint little ottos (or are they oscars?) which now clutter up the house so badly

Well, poor Noel cannot afford to live in England any longer, so there was *nobody* to tell me what to do with Carrie until you sent me Tom's letter And I was just about to give her all the *wrong* advice! Because I *did* have misgivings about her wanting to do Medicine Such a noble profession, of course! But I *never* realised what a dreadful state it had got into and that you needed young women so badly Not until I read Tom's letter It used to be so different when I was young Why, I remember that *all* my doctor friends used to be intense about their work and I cannot remember *one* who wanted to play with first-stage rockets (whatever *they* are) instead of looking after his patients But I am sure that's all because today the poor boys are "dragged" and "pushed" and "bullied" and even "*cheated*" into the profession, instead of being allowed to stay at home No wonder they become such bad doctors But my dear Richard, you really must put poor Tom's mind at rest. There is still Carrie, and some of her friends, who really *want* to do Medicine and you cannot imagine how wonderfully intense they feel about it and with so many lives entrusted to them, let us hope that they always will do (And surely there must be a *few* young men left like that!)

But then, I must confess to you, there *was* also this question of marriage that kept worrying me - Not that Carrie ever consults me or Sylvia about things like that but watching our own Dr Misgust, who comes to write up Jeremy for his sleeping-pills, I did become quite perturbed Because the poor man is always so terribly bad-tempered never a moment even to sit down, though he is really wonderfully kind and insists on sending us to the very best hospitals even when it's only a sore throat. And when he did come to tea the other day I felt *so* sorry for his poor dear wife, because I am sure that she wasn't nearly so interested in cancer and yellow fever as Jeremy and I and the Vicar and Mrs Appleby and they do have tea together quite often But I see now how different it will be for Carrie After all, it *is* quite likely that she will marry a doctor and then, as Tom says, she and her husband will be able to forget about their marriage now and then and talk "shop" And when I think of all my friends and their husbands who have had *nothing* to talk about for the last thirty years, and when I have to listen to Jeremy who still talks tinned fruit (although it's five years now since he retired) every time I want to talk to him about something *interesting*, well, isn't it going to be fun for Carrie and her husband to talk the *same* "shop" to each other any time they feel like talking? But, of course, Carrie might not marry a doctor only why does Tom say that if she didn't, it would have to be a poor half-wit? Not that I think that all husbands need to be intelligent, or even bright but it is really distressing to think that there are only a few Englishmen left who are able to grasp that being a doctor one cannot *help* learning something about Medicine (Even those poor bullied young men couldn't help that) But if things really *are* as bad as all that, how fortunate for Carrie that she will be able to pick one of the few, and that she will recognise the others in time—because superficially most of them appear quite *normal* And, of course, if she *did* marry a foreigner, like Louis (Sylvia's second) or Adam (her fourth), then it wouldn't matter any longer if he was a bit more or a bit less mad, because, I suppose, there would be other things

---

* Reproduced in the Widdicombe File, March 1

Well, whether one marries a doctor or not, Tom is so right in saying that a husband shouldn't be " just something handy around the house ", as most husbands are nowadays And how nice that Carrie's husband will never have to be just that because, with other things on her mind, he could almost *run* the house (with a little supervision at first) and wouldn't that be fun for him, and, I'm sure, so much better for the house too?

And thinking of husbands made me think of children because, however intense Carrie might feel about her Medicine and about her husband, in this modern world a double life like that will hardly be enough to keep an intelligent young woman like her fully occupied So she will have plenty of children And when I read in Tom's letter about all the *horrible* brainwashing and bullying that goes on in the schools, I thought to myself that we really must make quite sure that at least they have a nice and interesting homelife And if Caroline can go out to work and relax, and doesn't have to stay at home and just look after the children day after day after day, and year after year after year, and get grumpier and grumpier, and wearier and wearier, and duller and older all the time, well, then that won't be too difficult Of course, Jeremy and I, and Sylvia and Ron (her present and fifth), and even perhaps her husband's parents and grandparents will all have to give her a hand but won't it be fun for the children to have a real *family* about, and not just a lot of old relatives like most other children And you cannot imagine, my dear Richard, how much we are all looking forward to that because I don't think you young doctors realise that, now that you keep us old people so wonderfully fit, doing nothing does get a little monotonous And though I may not have been much good at educating my own children, I did always take the best advice (like Noel's and Tom's), and I did always try to learn by watching other children whose parents did a lot of educating (And that wasn't usually difficult, because they always came to our house whenever they could get away from their own homes)

Well, when I told Carrie all this, she said that, though it was a *great* help to get all this encouragement from such an experienced person as Tom, not all doctors were as tolerant and farsighted as he, and that some were positively *obtuse* and didn't like the *idea* of what they called " female competition " So I made a point of asking our Dr Misgust next time he came and he got so excited that he spent a full five minutes (which he could have spent examining his next three patients) telling me that women were all right to look after women, but that they just didn't *understand* men And I said that was exactly what I thought would make doctoring so nice for Caroline because men, who do understand men, don't seem to care for them a bit and it must be so much nicer to look after patients one likes And that made Dr Misgust quite angry at first (because he hadn't thought of it before) and he said that it showed how illogical women were (But, of course, women are much more logical than men because when they do something for the sake of logic they usually have a good reason of their own as well) In the end he cheered up quite a bit and before he left he had to admit that Medicine hasn't been the same since women were first allowed to qualify And when I began to think of all the wonderful discoveries doctors have made since then (even if not *all* were women) I really felt quite proud

After this all that kept worrying me was the bit in Tom's letter about filling in forms and " dashing to the four corners of the Realm " to try and find a vacancy But there again, I said to myself, with all those great universities and hospitals absolutely packed with men, and men being so logical, it couldn't be as bad as all that And it wasn't Because last week Jeremy went to see Sir Harold Vymme in Harley Street for his quarterly blood-pressure and after he had had it all checked and adjusted I told Sir Harold about Carrie wanting to study Medicine at St Nicholas' (which is practically run by Sir Harold's secretary) Well, at first he wasn't a bit hopeful and I must confess to you, my dear Richard, that when he started telling us in his wonderfully melancholy voice about all the poor young men who wanted to get in, and about them having to earn a living later on, and about having only one vacancy for three, and whether I thought it fair to keep one of them out to get Carrie in well, I suddenly felt quite ashamed of myself And I said I would call in Carrie and put it all to her in this way, and that I was sure that when I had done that, she would want to change her mind And so I did call in Carrie but it wasn't Carrie who changed her mind It was Sir Harold Because just as I was coming to the bit about those nice young men wanting to get in (and the tears began to roll down Carrie's cheeks) Sir Harold suddenly remembered that it was just remotely possible that he may have forgotten about one particular vacancy And that brought just the faintest little smile to Carrie's face and I know it's not for me to say, but *she really does look so pretty every time she does that* Her mouth opens just a tiny bit and but I mustn't stray from what I was saying Or rather, I wasn't saying very much by then, because the more Sir Harold thought about it, the more sure he seemed that there was, in fact, a place still open But of course he was quite firm with Carrie and he said that she would have to come and see *him in his office first And Carrie said that she* would love to go, even if there was not the slightest chance of her staying on But by then Sir Harold was quite positive that there would be And Tom really mustn't be too unfair on men (even if they are only logical most of the time), because this only happened last week and today Carrie telephoned and said that it was all arranged for her to start at St Nicholas' next autumn And whatever happens, my dear Richard, you really *mustn't* let Tom chain himself to the Palace railings That was all right with only a king living there, but now that even *that* job has to be done by a young woman, it really wouldn't be fair But do thank him again for all his wonderful encouragement and I am letting Mrs Appleby and all my friends read his letter so that they can all benefit from his advice

Goodbye for now, my dear Richard, and give my love to all the family

Your affectionate old friend,

MARY WORTHINGTON

Conferences

HORMONES AND ATHEROSCLEROSIS

A conference sponsored by the endocrinology and heart sections of the National Institutes of Health was held from March 11 to 14 at Brighton, Utah, under the general chairmanship of Dr Gregory Pincus (Worcester, Mass)

Cholesterol Metabolism

Prof Sune Bergstrom (Lund), who considered the influence of intestinal flora on the excretion of cholesterol and bile acid, showed that hypothyroid rats excrete almost pure cholic acid, whereas *hyperthyroid rats excrete mostly chenodeoxycholic* acid This difference may be due to stimulation of bacterial floral activity by the thyroid hormones He agreed that, although the liver is the primary site for cholesterol degradation, all tissues have the capacity to degrade cholesterol into bile acid

Dr G S Boyd (Edinburgh) showed that in rats thiouracil has an extrathyroidal effect in elevating plasma-cholesterol Triiodothyronine and tri- and tetra-iodothyroacetic acids cause selective increase of the oxygen requirements of isolated myocardium, and the administration of tri-iodothyroacetic acid to hypercholesterolæmic rats reduces both plasma-cholesterol and lipid deposition in the aorta

Dr J E Rall (Bethesda) demonstrated that low concentrations of circulating thyroxine are bound between the alpha-1- and alpha-2-globulin fractions, but that higher concentrations are apparently attached to albumin Sex hormones can influence thyroid activity by altering the protein-binding capacity and thus altering the concentration of circulating free thyroxine

Arterial Wall and Cholesterol Transport

No critical level of blood-cholesterol has been observed for the development of experimental atheroma, and hypercholesterolæmia induced by alloxan or detergents is not often followed by atheromatous lesions, these observations, and the irregular distribution of atheromatous lesions, do not accord well, in the opinion of Dr R L Holman (New Orleans), with the filtration theory of the pathogenesis of atheroma He emphasised the importance of the arterial wall, indicating that atherosclerosis is a gradually progressive process with well-defined histological stages

Dr N T Werthessen (San Antonio) showed that the accumulation of cholesterol in the isolated perfused aorta is directly related to the initial concentration of cholesterol and to the glucose content of the aorta

Dr D B Zilversmit (Memphis) has shown by tracer studies that all phospholipids have a higher specific activity in the aorta than in the plasma He believes that excess phosphatide in the aorta is probably due to local synthesis It is possible that once the process of arterial lipogenesis is set into motion, reduction of hypercholesterolæmia will have little effect

Dr Leon Hellman (New York), who has cannulated the left thoracic duct in humans, reported the results of simultaneous analyses of the plasma and lymphatic lipids In normal people and in hypercholesterolæmic non-lipæmic patients, the plasma specific activity of ^{14}C-labelled free cholesterol is greater than that of esterified cholesterol, but in hypercholesterolæmic hyperlipæmic subjects the specific activity of ^{14}C-labelled ester cholesterol is greater This might suggest the possibility of a defect at the intestinal level of absorption. Dr Hellman indicated that the fall in plasma-cholesterol following corn-oil administration is more directly related to excretion of sterols than to that of bile acids

Hormones and Experimental Atherosclerosis

Dr David Adlersberg (New York) showed that cortisone and prednisone increase plasma-free-cholesterol, beta-lipoprotein cholesterol, and plasma-phospholipids The combination of cortisone with cholesterol feeding causes greater hypercholesterolæmia but less atherosclerosis in animals fed cholesterol alone He suggested that this may be due to a decrease in arterial permeability produced by cortisone, and in support of this the simultaneous administration of hyaluronidase increased the degree of atherosclerosis

Dr S O Byers (San Francisco) reported that rats which were intermittently stressed by contact with an electrical charge at varying points in their cages, and were therefore very active physically, had no change in the plasma cholesterol or phospholipids, but had shortened clotting-times when compared with a control group

Dr Marmorston (Los Angeles) reported that in dogs a single injection of corticotrophin (A C T H) resulted subsequently in a greater hypercholesterolæmic response to cholesterol and thiouracil feeding than if no corticotrophin had been administered Extensive atheroma developed in these dogs throughout the vascular tree and some even had cerebral hæmorrhage A flaccid paralysis was observed in other dogs, but it was not clear whether this was related to the cerebrovascular lesions

Dr R Pick (Chicago) believes that a decrease in the cholesterol/phospholipid ratio is more closely related to the experimental regression of atherosclerotic lesions in the chick than any other lipid measurement All her experimental observations on the chick have emphasised that the aorta is more sensitive to the production and reduction of lipid-rich lesions than the coronary arteries

Dr R H Furman (Oklahoma City) reported a case of biliary cirrhosis in a woman, aged 30, in whom the plasma-cholesterol increased to 3000 mg per 100 ml but the cholesterol/phospholipid ratio remained less than unity At necropsy there was atherosclerosis in the aorta but the coronary arteries were healthy

Hormones and the Blood Lipids

Dr Joseph Shifter (Philadelphia) reported further studies on a lipid-mobilising factor that can be demonstrated in the posterior pituitary of hogs and is apparently independent of known pituitary hormones Parenteral injection of lipid-mobilising factor produces hyperlipæmia in the systemic circulation in the presence of liver damage, but with a healthy liver this hyperlipæmia is confined to the portal circulation

Dr R H Roseman (San Francisco) reported that the plasma-cholesterol levels were increased and that the clotting-times were decreased in accountants when they were undergoing the stress of having to balance quarterly accounts

Dr David Adlersberg (New York) emphasised the association of acute pancreatitis with hyperlipæmia and felt that the role of glucagon in the regulation of lipid metabolism needed considerable clarification Dr G S Boyd (Edinburgh) did not observe destruction of the alpha-cells following cobalt chloride administration, which resulted in a rise in the plasma-cholesterol and a fatty liver in his rabbits Dr E Strisower (Berkeley) reported that the concentration of high density lipoproteins decreased after the administration of very large doses of desiccated thyroid, thyroxine, and triiodothyronine to euthyroid patients Dr M F Oliver (Edinburgh) had also observed a decrease in the alpha-lipoprotein concentration with large doses of thyroxine and triiodothyronine, but he felt that this might be a dose effect since the alpha-lipoprotein level was actually increased with smaller doses of these thyroid hormones

Dr Howard Eder (New York) reported that a low dose of methyl testosterone did not necessarily produce much change in the total cholesterol in the plasma, although the beta/alpha-lipoprotein ratio is increased Similarly, he had observed a decrease in the beta/alpha-lipoprotein ratio without any very significant change in plasma-total-cholesterol following the administration of certain weak œstrogens He raised the question whether a compound which allowed a change in the lipoprotein ratio but not in total cholesterol was of any value in influencing atherosclerosis

Clinical Biological Relationship

Dr A R P **Walker** (Johannesburg) emphasised the rarity of coronary-artery disease in the Bantu Cerebral atherosclerosis and hypertension are common and often severe The principal differences from Western nations are in the diet and physical activity There is a higher concentration of unesterified fatty acids, greater fibrinolytic activity, and greater œstrogen excretion in the Bantu than in the White A third of adult male Bantus had gynæcomastia, but as yet there is no definite correlation with the incidence of liver disease Liver disease probably contributes to the rarity of atherosclerosis in the Bantu, but this is probably mostly determined by the diet

Dr M F **Oliver** (Edinburgh) indicated that various thyroid analogues decreased the plasma-cholesterol without apparently increasing the basal metabolic rate, but so far these had proved to be unsuitable since the cholesterol-lowering effect could not be maintained beyond a few weeks and angina was aggravated in a quarter of his patients Following the clinical trial of several weak œstrogens, he concluded that it was not yet possible to dissociate the cholesterol-lowering action from their feminising effects (Dr **Roger Robinson** [Worcester, Mass] and Dr **Victor Drill** [Chicago] had found the same) Although the administration of ethinyl œstradiol for two and a half years to 50 men with myocardial infarction had reduced the plasma-lipid levels, there was no difference in morbidity and mortality from further coronary episodes between these men and another 50 receiving lactose

Dr J **Stamler** (Chicago) reported similar results from a group of about 100 men who had received 'Premarin' (conjugated œstrogens) over a three-year period There was no definite evidence, therefore, that the long-continued reduction of the plasma-lipids improved the prognosis

NEOPLASIA

A **conference** on Neoplasia organised by the postgraduate medical education committee of the University of Glasgow and the Royal Faculty of Physicians and Surgeons was held on March 26–28

General Concepts

Dr **Philip Peacock** said that the first rational idea of causation was Percival Pott's observations on chimney-sweeps' cancer of the scrotum Tumours arise in all animals, but some tumours common in man seem to be rare in other animals Theoretically cancer can start from one cell, but the earliest case which Dr Peacock has seen was multicentric In this case, in addition to the definite neoplastic foci there were areas of retained sebaceous secretion, and the possibility of this being carcinogenic must be considered, especially in view of recent suggestions that cholesterol is a carcinogen Perhaps cholesterol can be transformed into methyl cholanthrene Except in a few industrial cases the cause of carcinoma is unknown, and even where the carcinogen is recognised, the final process remains to be discovered Contaminants of so-called carcinogens may be the active agents

Some virus-induced tumours regress spontaneously, the reason for this may be in the hereditary transmission of the tumour, and an additive factor may be involved Dr Peacock's concept of neoplasia is that cancer is an alternative mode of existence for a cell which is threatened by death It may be due to imbalance of cell constituents

D N A

Prof J N **Davidson** reviewed the knowledge of cell substances, notably those of the nucleus Of these, desoxyribonucleic acid (D N A) is the most important The amount of D N A in the cell is remarkably constant in different organs except the liver, where it is increased Many tumour cells have more D N A than normal cells D N A may actually alter the characteristics of cultures and even of organisms For example, D N A from a mutant added to a sensitive culture will produce mutant cells in the culture D N A from phage may alter *Escherichia coli*, to produce further phage

Endogenous and Industrial Tumours

Dr B D **Pullinger** said that some tumours now considered endogenous may eventually be removed from this group by further research Squamous carcinoma of the lung may or may not be endogenous, but it seems likely that neoplasia of the scrotum is exogenous, as it occurs mainly in the lower social classes and the agent can probably be washed off The virus tumours of animals are difficult to classify Some tumours—notably polyposis coli and retinoblastoma—are hereditary Some—notably carcinoma of the breast—appear to be familial

It is impossible to study hereditary tumours in man, because of their irregular breeding, but it may be possible to produce tumours in animals which are highly inbred The reason for tumour formation may be senescence of the cell or the presence of internal substances which irritate the cell Recently many mammary tumours have been associated with cholesterol deposits Cholesterol has caused carcinoma in the bladders of mice It has recently been shown that carcinoma can be produced locally by the injection of œstrogen

Dr A T **Doig** spoke of industrial cancer The possible factors involved are tar, pitch, shale-oil, asbestos, X rays, ultra violet rays, arsenic, and chromates Radium and radioactive materials have become important Latent periods may be long In some industries non-carcinogenic materials may be substituted, and in some the process can be properly screened Dr Doig made a strong plea for the notification of all cases of possible industrial cancer, so that the conditions of work might be inspected

Reticulo-endothelial System

Dr R I **Shaw Dunn** classified tumours of lymphoid tissue into (1) Hodgkin's disease, with subdivisions of typical, atypical, Hodgkin's sarcoma, and Brill's disease, (2) lymphosarcoma, which may be small- or large-celled, (3) lymphoreticulosarcoma, (4) reticular cell sarcoma, and (5) miscellaneous

Dr A **Brown** dealt with the clinical picture of "reticulosis" Leukæmia is merely a symptom of several different diseases There has been a gross increase in this condition after atomic bombing, and in radiologists, but its incidence has also increased in the general population over the same period The prognosis of these diseases of the reticulo-endothelial system is poor, the average survival being two and a half years—though patients with Hodgkin's disease may survive for several years and those with chronic leukæmia for up to twenty years The management of these lesions is non-specific X rays may be used at the local site of a disease, chemotherapy is generally reserved for radioresistant or generalised lesions Dr Brown favours nitrogen mustard by injection, but recent results with tretamine (T E M) and busulphan ('Myleran') are poor Anti-metabolites, such as folic-acid antagonists and purine derivatives, are giving some beneficial results

Regional Cancer

Prostate

Mr W B **Stirling** said that in prostatic cancer the serum-acid-phosphatase is increased in 90% of cases Only 5% of the patients are suitable for radical prostatectomy, the rest are treated by stilbœstrol Without treatment, the average duration of the disease is fifteen months, with 9% five-year survivals, after stilbœstrol the average duration is forty-five months, with 27% five-year survivals Adrenalectomy and hypophysectomy yield poor results

Liver

Prof J W ORR (Birmingham) pointed out that, in Africa, primary cancer of the liver is found in 1% of all necropsies, compared with 0 1% in Europe In South China and in Indonesia it is common in the natives but rare in Europeans The age and sex distribution is explicable by the survival-rates of these populations Race seems to have little effect, the Africans in America have lost their tendency to primary liver cancer This uneven incidence of carcinoma of the liver may be explained by a dietetic deficiency or by a toxic factor Primary liver tumours are not common in animals, but can be induced by butter yellow and similar substances The tumours that develop are similar to the primary tumours in man It seems likely that carcinoma develops on a process of regeneration

Stomach

Prof C F W ILLINGWORTH remarked on the poor results of the treatment of carcinoma of the stomach—a disease which now causes the death of 300 people a week in the United Kingdom The five-year survival-rate is only 2 7% in all diagnosed cases, and 12% in those who have had gastric resection The ætiology is unknown, and tumours cannot be produced in animals by feeding carcinogens It is unlikely that gastric ulcers lead to cancer in more than 5% of cases of ulcer In treatment radical total gastrectomy is unsatisfactory, and partial gastrectomy is probably best. Exfoliative cytology does not add many to the cases diagnosed by other means Routine test of the stool for occult blood may be a useful screening-test for gastric cancer

Thyroid

Dr E M MCGIRR said that cancer of the thyroid gland accounted for only 0 4% of deaths from malignant disease At all ages it affects females more than males There are three main types (1) differentiated (papillary follicular, and Hurthl-cell adenocarcinoma), (2) non-differentiated, and (3) miscellaneous Surgery has not given very good results, and radioactive iodine is suitable for only 10% of the cases

FREEZING AND DRYING

THE second international symposium on freezing and drying was held, under the auspices of the Institute of Biology, in London on April 1 and 2

General Topics

Dr H T MERYMAN (U S.A) discussed the mechanical and biochemical changes during freezing in biological systems He felt that a balance must be reached between rapid cooling (in which mechanical damage is maximal) and slow cooling (in which biochemical damage is maximal) The use of additives, such as glycerin, may be rendered unnecessary by uniformity in freezing and thawing

The paper by Prof N KALABUKHOV (U S S R) was read by Dr A U Smith It dealt with the problems of undercooling, freezing, and vitrifying whole animals Experiments were described in which bats were undercooled to −5 to −7°C, and survived storage at these temperatures for periods up to several days At −4 3°C the heart-rate of bats was about 8 beats a minute, compared with the normal rate of 400

Microorganisms

Dr W J SCOTT (Australia) discussed the role of protective agents in storing freeze-dried bacteria One cause of death is the intracellular reaction of carbonyl with amino groups—known as the browning reaction. This occurs in dried preparations, and the water formed during the reaction accelerates the process Glucose or ribose in the medium improves the viable count immediately after freeze-drying, but exerts a deleterious effect on stored organisms Their corresponding reduction compounds (sorbitol and ribitol) give protection without facilitating the browning reaction Addition of aminoacids to the freezing-mixtures to compete for the carbonyl groups is another means of protection, Lysine and sodium glutamate have been found useful in this respect Along similar lines sulphur dioxide, which reacts with ketone and aldehyde groups, exerts a protective action

Dr R. I N GREAVES described some factors which influence the stability of freeze-dried cultures, with particular reference to the browning reaction Dried cultures have been boiled to assess the effects of various drying media on their stability when stored for long periods Glucose in the medium gives high initial survival-rates, but the dried cultures are very heat-sensitive The greatest resistance to high temperatures was found in media consisting of 5% sodium glutamate in 5% dextran solution

Prof D GRIEFF (U S.A) talked of the effects of freezing, low-temperature storage, and drying by vacuum sublimation on the activities of viruses and cellular particulates Viruses showed less loss of infectivity when they were dried from the vitreous, rather than the crystalline, state The activity of mitochondria, measured by their capacity for oxidative phosphorylation, was better retained after slow than after rapid freezing This is possibly related to the preservation of the integrity of mitochondrial membranes

Miss B L BRADY described observations on the freeze-drying of yeasts, which is used as an ancillary method to maintain the national collection of yeast cultures With freeze-drying little difference is noted between the survival-rates of sporing and of non-sporing cells, and between haploid and diploid organisms There are generic differences in survival-rates After freeze-drying no change has been noted in vitamin and aminoacid requirements of the yeasts

Grafts

Commander G W HYATT (U S A) spoke of experience in maintaining a bank of freeze-dried human cadaveric tissues for use in surgery Skin, dura, fascia, bone, and arteries are removed aseptically from selected sites The tissues are placed in a medium containing serum and then freeze-dried at 4°C for six weeks, at the end of which the moisture content has fallen to 2 7–3 5% The materials are stored in sealed vessels at room temperature until needed. Bone stored for up to five years has been used successfully

Prof C G ROB described the experience of his surgical unit with freeze-dried arterial grafts Of the last 394 arterial reconstructions, 178 were carried out with homologous tissue transplants Frozen arteries were used in 78 of these, and freeze-dried arteries in 100 The two types of material take equally well The criterion of success is the absence of thrombosis, and anticoagulant drugs are an essential part of postoperative routine.

Colonel F HENAFF (France) discussed freeze-drying associated with corneal grafts The freeze-dried corneas are undoubtedly non-viable, but both full-thickness and lamellar grafts have successfully been carried out with homologous and heterologous (dog) material

Dr A S PARKES discussed the freeze-drying of viable grafts Rat ovaries are good test material because when they are grafted they become physiologically active after a few days Frozen ovaries retain their activity for at least two years when stored in 15% glycerin at −79°C At this temperature viability has been maintained although the tissues are effectively dry, because their water is in the form of ice The problems are how to remove the ice, and what to do with the residual glycerin High concentrations of glycerin are toxic at room temperature This is therefore an unsuitable component of freeze-drying media An ideal protective agent would protect against freezing, be non-toxic, and sublimate with ice during the drying process To this end, methanol has been tested on rat ovarian tissue in freezing experiments Viable grafts have been obtained after ovaries have been kept for a few hours in methanol at −20°C

In England Now

A Running Commentary by Peripatetic Correspondents

I SPENT most of Easter in a new way—on a protest march A new experience for one so apolitical A most impressive experience So many sorts and conditions of men, all trudging along in the foul holiday weather to Aldermaston I couldn't stay the whole course, for family reasons, but managed Good Friday and the Easter Monday march to Aldermaston itself The skiffle groups and the beards weren't surprising, there were plenty of obvious vegetarian, teetotal, sandal-wearing oddities, but the real surprise was the number of normal, ordinary, shabby people, the kind you see on a bus or in your surgeries, far outnumbering the peculiars The profession seemed a trifle thinly represented, though I had two medically qualified companions on Friday and one on Monday

Thirteen miles is a fair stretch, and there were many footsore blistered plodders by the end An efficient-looking motorcyclist with a Red Cross flag was in evidence, and I saw one girl with actually bleeding feet waiting for his attention The organisation was extraordinarily well done and not obtrusive The marshals wore tangerine armbands and appeared at intervals, shepherding the stragglers and keeping the column more or less in triple file It seemed endless, winding along over hills and bridges—you could see the big black square banner at the head, but not the tail, just a three-deep switchback of people who felt strongly enough to be there There was a policeman every 100 yards or so, friendly and smiling, but efficient—a collie, one felt, who would stand no nonsense from his flock but who had their interests at heart The considerable traffic wasn't allowed to jostle us too closely and often had to wait

When we got to the precincts of Aldermaston we marched in silence—fairly strictly observed for the most part, though there were some inveterate chatterers behind us Aldermaston seemed a blend of science fiction and normal life The high wire, dogs, armed guards, and some very functional buildings all fitted in, but there was a lake, and some blocks of buildings in contemporary colours like modern flats, which looked out of place We marched round it, silent, a bit grim, tired and cold There were thousands of spectators, nearly all were friendly, and many, from Trafalgar Square to Aldermaston, smiled and clapped and shouted encouragement Some of course just "gawped" indifferently, but the overwhelming impression was of support

The journey home took *hours*, but for all that it was a satisfying way of spending Bank Holiday Next morning my five-year-old said "Did you stop them?" I couldn't think what he was getting at and said ungrammatically "Stop who?" "The Government," he said, "from making H-bombs" I had to confess we hadn't—yet

* * *

Some years ago we designed a controlled trial to assess the effect of winter chemoprophylaxis on chronic bronchitics in a community Only subjects who were severely affected were included and they were given either real or dummy tablets of a certain drug according to the dictates of our statistician

Last year, when we revisited the community to invite its members to take part in a further investigation, we were dismayed by their apparent reluctance to cooperate with us again We soon discovered that their hesitation was due to apprehension lest we were about to issue more tablets, for, while we *had* found the results of the previous trial statistically insignificant, the subjects themselves had carried out their own analysis in the years that followed and come to a highly significant conclusion almost all who had taken *any* of our tablets were now either very much worse or dead

* * *

Archie White had been a sore trial to many of us A young man with a duodenal ulcer, he had fallen in with a gang of car thieves and as a result spent three months in gaol Unimpressed by this experience he made further unsuccessful excursions into the illicit car trade and again enjoyed Her Majesty's hospitality for a year Soon afterwards he appeared at my clinic and I sternly warned him that he must mend his ways or he would find himself breaking stones in penal servitude It was clear that Archie found this prospect unattractive and he promised to abandon his old associates Later I heard that he had a job with a firm of road contractors

I saw nothing more of him till last week Held up in a traffic block I was idly gazing at a group of workmen who were repairing the road when I saw the figure of Archie White bending down to pick up a large cobblestone He looked up, recognised me immediately, and reaching for a hammer proceeded with a rueful shake of his head to break the stone As I drove past he favoured me with a splendid wink and a touch of his cap

* * *

I always enjoyed walking on stilts Since I reached an age when it no longer seemed normal to possess a pair I have longed for the time when my son would be old enough to own some

Recently I bought a pair They were made of red tubular steel and were much more handsome than the home-made ones I had used in my youth I hid them in the cellar to await his birthday, but I was so excited about them that I found it difficult to keep them there I admit that once or twice, after he had gone to bed, I fetched them and walked them round the drawing-room After all, I had to make sure of my superiority before he received them

Two days before his birthday my son announced that he was so glad he was receiving a clockwork train for his birthday I remembered in horror that, months before, I had promised him a train A train there would have to be

Now the stilts must remain in the cellar until Christmas I long for them more and more, but will content myself with nocturnal walks on them round the garden on summer evenings Perhaps it is better so Toys are best when they are not shared, and I never was enthusiastic about clockwork trains

* * *

We thought we finally decided to buy the house because it had two gates We had always hated backing the car into the road and at last we had a drive encircling a green lawn We kept our gates open and drove in at one and out of the other But patches of brown appeared on the lawn and ruined its appearance Investigation disclosed that every passing dog entered one of our gates and left by the other, leaving his mark on the lawn in passing When, for experimental purposes, we left one gate shut, no dog entered It had not occurred to us that dogs would share our liking for double gates Their motives must be purely psychological A dog does not need to exit in reverse through a single gate

We decided that our motives were psychological too We now keep one gate closed and through the other we reverse the car as before What we really like of course (and this must be the real reason why we bought the house) is looking out of the window on to a green lawn In that, at least, we differ from the dogs, except our own, who fortunately shares our respect

* * *

News from School—On Friday there was for me the great event of the term, particularly as there were only four other dinner jackets there It was in the gym of a school at ———— It started at 7 30 sharp At that hour all the males were sitting self consciously round the walls At 7 31 the females trooped in, not quite in crocodile, but possibly in height order from the front After we had sat there for five minutes more, with the mediocre band playing moderately hard, I leaped to my feet, singled out a female on the other side, and gave a demonstration *of the Gay* Gordons with her She had only done it once before *After* that all the earnest, dark-suited, open-neck-shirted boys surged to thei feet as one, and there was a hubbub of intelligent conversation My partner thought I was a sort of Carruthers and I did not disillusion her We danced until 9 45, when my house-master had ordered us to start back By that time I knew her first name, just *She* doesn't know mine I hope that all she will remember is the brilliant conversation, the unobtrusively perfect dancing, and the perfect breeding of the charming young gentleman who whisked her round the floo so effortlessly that March night She told me her father had forbidden her to rock and roll, so we rocked and rolled After that we parted, she with a wistful look in her eye

Letters to the Editor

A BALANCED HOSPITAL COMMUNITY

SIR,—A consultant colleague greeted me on the morning of April 5 with the remark, "This man McKeown is talking sense about hospitals" That sentiment will surely be echoed by all who have studied the needs of our hospital service I write, however, to remind your readers that the views so ably supported by Professor McKeown's figures for Birmingham were one of the basic reasons for introducing a regional and group hospital service Experts writing as early as 1938 in the prize-winning article on a hospital service, The Walton Plan,[1] made a plea for

> " real general hospitals which will admit all kinds of cases including infectious fevers, tuberculosis, maternity, mental disease, and sick children. The hospital will have 1000 to 1200 beds and serve about 100,000 people. A general hospital of this kind will be able to care for a large number of chronic cases without exhausting the interest of the staff There is a great tendency to exaggerate the degree of infirmity of those who are merely old as under the scheme there will be no acute hospital, so there will be no need for the corollary, the chronic hospital"

This conception became the basis of all discussions on future hospitals, and writing in 1942 in *Health for All* I was able to "make another assumption, that all hospitals in a socialised service will be general hospitals taking every type of case" Indeed one had in mind and has always advocated a system of general district hospitals which would assume the primary responsibility, in the closest cooperation with the general practitioners, for all the hospital and specialist care needed by its unit of population It could not effectively deal with everything on the spot, but it could take the responsibility for deciding how each case should be dealt with most efficiently (from the sick person's angle) either because it had the resources or could direct the patient to the necessary resources (This is of course the principle on which our group laboratories which give an open-access service operate, with all the reference laboratories to take the more unusual cases from them)

In short, the theory of twenty years is shown to be correct by general experience and now by Professor McKeown's excellent article But why do we seem so far from the ideal? Is it the profession which has not realised this need and so has not put the right pressure on the lay and financial authorities to amalgamate and reorientate our hospitals? Are we still bound by ideas nearly as old as our hospitals (more than half of them one hundred years old) and so unable to advise our lay committees with the authority that would make them move? I hope Professor McKeown's article will set the ball rolling

Kingston Hospital,
Kingston-upon-Thames, Surrey

D STARK MURRAY

"THESE DYING DISEASES"

SIR,—Dr Ambrose King's thoughtful article on venereal diseases (March 29) is timely and shows clearly the difficulties which are rapidly approaching in the present venereal-disease service In spite of Dr King's rosy picture for the future of this branch of medicine, the hard fact remains that the young man with at least 35 years of active life in front of him obviously does not consider that venereology is for him, and the service as we know it is slowly but inevitably disintegrating The time has surely come for fundamental reorganisation in order to have a workable scheme ready for the care of these patients when the present system breaks down.

Venereology differs from most other specialised branches of clinical medicine in that it is specialisation in a group of disease-processes, whereas other specialists are concerned with all types of illness and alteration of function which may affect the part of the body in which they are particularly interested The difficulties attendant upon specialisation in a disease have recently been seen with tuberculosis, and the same trend is happening with venereal disease. It is probably this and the relatively small number of new cases seen at each clinic that discourage recruits, rather than such factors as hours of work, &c.

From Dr King's figures, the majority of the cases attending the clinics are not suffering from venereal disease, the cases with non-specific urethritis are now the major problem, and these are in need of general medical investigation and care Most cases of late syphilis are treated by the physician specialising in the organ mainly affected and not by the venereologist In the same way, the treatment of all these patients could be taken over by the appropriate specialist. Patients presenting with skin manifestations could be treated by the dermatologist, congenital infection by the pædiatrician, genitourinary discharge by the genitourinary specialist or the gynæcologist, non-specific urethritis by the general physician, and so on This is virtually what has happened in the case of tuberculosis

Two problems remain one is the patient with a discharge or fear of infection, and the other is preventive measures With regard to the first, since 1948 everybody in this country should have his own family doctor, and it is to him that the patient should go, being referred by the practitioner if necessary to the appropriate specialist With regard to the control of venereal disease, notification, with due safeguards for secrecy, could be introduced by appropriate legislation so that control can be undertaken by the department best equipped for doing this—namely, the medical officer of health and his team

Thus, with the inevitable running down of the venereal disease service, the duties formerly undertaken by the venereologist would gradually pass back into the medical fold and the stigma of "special clinics" and special wards would disappear

These ideas are put forward not in any spirit derogatory to the present venereologists but as a basis for trying to deal with a problem which must be tackled within the next few years when the number retiring exceeds the number of recruits

Oxford.

H. R. VICKERS

CONSULTANT DISTRIBUTION

SIR,—It is true, as Dr Joules says (April 5), that facts are gradually emerging which tend to show some inequity of consultant distribution in the country It is not true, as Dr Joules imputes, that the medical profession has failed to strive for an increase in consultant establishments Indeed, even in Dr Joules' own region (which, according to details given on p 748 of your same issue, must be one of the most heavily staffed in the country), there has been considerable agitation in the medical committee to secure a review of the consultant establishment.

It seems that one of the objects of Dr Joules' letter is to imply that those boards with the lowest consultant staffing ratio may have been influenced by "very powerful medical advisory committees" The figures given in Dr Joules' letter and in your summary of a written reply by the Minister of Health on March 21 are too sparse for any proper conclusions to be drawn. For example, the table you publish makes no mention of the teaching hospital beds in the various regions, nor does it give a true idea of the number of consultant sessions in each region. Furthermore, we are given no idea of the numbers of chronic sick beds (which show considerable variation) in the different regions, or of the S H M O establishment

---

[1] *Med Today*, 1939, 2, 2.

These and many other statistical details will need to be collected before we can draw any valid conclusions about the opportunities for expansion in the various regions I am, however, heartened by the fact that the figures thus far available suggest that the consultants and specialists committees have been correct in their contention that an increase in senior staffing of the hospital service is necessary

There is one important aspect of this problem on which we require much fuller information Whilst the Parliamentary answers reported in *The Lancet* give scanty information about the present staffing ratios of different regions, they give absolutely no information at all about the state of affairs at the inception of the National Health Service Is the apparently better staffing in certain areas attributable to the efforts of their regional boards since the appointed day, or is it wholly or largely due to such areas having inherited a number of hospitals which were well staffed before the N H S ? Further research may show that there has been a (relatively) greater increase in consultant establishments in the apparently worse-staffed areas On the other hand, it may be true that an area which began with a lower staffing ratio and bed/population ratio has, by virtue of its poor start, been handicapped in its endeavours to secure a bigger slice of the N H S cake

These are but a few of the many questions which occur to those medical men who seek fuller information on this extremely important subject The questions published by the chairman of the North West Metropolitan Regional Hospital Board (Jan 25, p 220), and which still remain unanswered, were framed with the object of elucidating this vexatious problem

Radlett, Herts REGINALD S MURLEY

THE COMMON COLD

SIR,—Dr Ritchie's articles (March 22) have interested me greatly I am convinced he is right in his thesis that the toxic manifestations of the common cold are caused by the enhanced virulence of the normal saprophytic flora of the pharynx I have reached an identical conclusion on the strength of experiences gathered from incidental treatment of a relatively small number of cases of common cold over the past two or three years

But you rightly point out in your annotation that there are risks involved in building up resistant strains by a widespread use of antibiotics Your readers may therefore be interested in knowing that results closely resembling Dr Ritchie's can be achieved without resort to antibiotics I have used for the resolution of the pharyngeal infection lozenges containing dequalinium chloride, which is a chemical agent active against a wide range of bacteria On some occasions a combination of this with lozenges containing chlorhexidine dihydrochloride proved more effective As indication for the systematic use of these compounds I regarded not only the developed sore throat but also dryness in the throat, the presence of which often remains unnoticed even by an observant sufferer

On two points I am inclined to differ from Dr Ritchie

One concerns the question of the virus The role and the behaviour of the virus is certainly no part of clinical observation The notion of the virus in common cold is derived from experimental work and has not yet been confirmed by laboratory techniques It seems to me that, within Dr Ritchie's thesis, the positing of the virus as the primary factor in common cold is before all else a conceptual device designed to account for the lowering of the body's resistance to its own bacterial flora, setting the stage for the unfolding of the clinical phenomenon, common cold

But epidemiological observations, such as van Loghem's in Holland, immunological considerations, and observations paying attention to psychological settings in which common cold occurs, or tends not to occur, all are somewhat difficult to reconcile with the virus ætiology of the common cold Certainly from the therapeutic point of view, in procedures such as Dr Ritchie's and my own, the virus may entirely be left out of account It is most impressive to observe how agents that are not known to affect a virus are capable of disposing of a developing cold within the shortest space of time, even within less than 24 hours, restoring the patient to full health If there be a virus, it behaves as if it did not exist

The other point is that Dr Ritchie regards as the second stage in the developing of the illness an attack by the nasal and pharyngeal flora My observation is that happenings on the nasal mucosa in common cold are distinct from those in the pharynx, and that only the pharyngeal flora is concerned in the attack

I hope later to set out my observations in some more detail and to propose an alternative theory to that of the virus ætiology of the common cold

London, W 1 JOSEPH ZELMANOWITS

SMOKING AND PEPTIC ULCER

SIR,—The following figures may be of interest in relation to the paper by Dr Doll and his colleagues (March 29) I quoted them at the recent symposium on carcinoma of the lung arranged by the N A P T

In a series of 7500 cases of peptic ulcer collected over a period of nearly ten years in the impaired lives registry of the Prudential Assurance Company, so far there have been 45 deaths certified as due to carcinoma, 18 of them were due to carcinoma of the bronchus, 17 to carcinoma of the stomach, and 10 to carcinoma in other situations This high incidence of carcinoma is not apparent in any other group of impaired lives

Since smoking has been suspected as a cause of carcinoma, both of the stomach and the bronchus, I feel that these figures, which I quoted by permission of the management of the Prudential Assurance Company, may be significant

London, W 1 E H HUDSON

ANOTHER "UNIVERSAL DIAGNOSTIC TEST"?

SIR,—I was very interested to read (April 5, p 749) about the work at the Johns Hopkins University School of Public Health on serum-mucoproteins

In diagnostic work of protein paper electrophoresis, we have certainly come to rely on the mucoprotein stain (P A S technique) to quite a considerable extent, since it is the most sensitive and easiest method of demonstrating what I have called *tissue necrosis and regeneration* [1] For the past four years the routine strips at this laboratory have been divided longitudinally into three, and a third stained respectively for total protein, mucoprotein, and lipoprotein The degree of tissue breakdown and repair (e g , in infections and trauma) is related to the intensity of the alpha-mucoprotein bands

I have associated tissue necrosis or degeneration with increase or emphasis of alpha-one-mucoprotein, and *tissue growth or regeneration with increased alpha-two-mucoprotein* The prognosis in many diseases seems to be related to an alteration in the ratio between alpha-one- and alpha-two-mucoproteins A prominent alpha-one-mucoprotein band carries a bad prognosis Alpha-one-mucoprotein is emphasised in many cases of hæmolytic diseases, heart-failure, steatorrhœa, malignant hypertension, some malignant diseases, some virus diseases, &c , and approaching death *Alpha-two-mucoprotein* is emphasised in childhood, pregnancy, neoplasm, arthritis, infarction, trauma, and renal disease

---

[1] Dagnall, P *Clin chim Acta*, 1957, 2, 391

The interesting points mentioned in your note are too numerous to discuss here There are some abnormal beta- and gamma-mucoproteins—e g, the unusually staining beta-mucoprotein in myxœdema, the gamma-myeloma-mucoproteins, and the mucoproteins of miscellaneous fluids, such as urine and pleural, peritoneal, and synovial fluids

Rewarding observations may also be made by relating increases in mucoprotein to the appropriate portion of the paper stained for total protein—e g, in rheumatoid arthritis the increase in alpha-two-mucoprotein is in excess of that shown on the strip stained for total protein These latter findings may prove to be of greater diagnostic importance than changes in the mucoproteins themselves

NEW METHOD OF PHENOBARBITONE ADMINISTRATION

Sir,—I cannot agree that Dr O'Connor (March 22) has really demonstrated anything

The mean daily dose of phenobarbitone in the control series was gr 2 8 daily, and with 'Spansule' treatment gr 5 8 The toxic effects noted with the patients receiving regular phenobarbitone were mainly subjective ones, which must be very difficult to evaluate in psychotic patients It would be reasonable to suppose that such symptoms might disappear if the dose of ordinary phenobarbitone were doubled This essential control is missing

Dr O'Connor must be unaware of the study by Butler et al [1] These workers showed that in man there was no significant difference in blood levels of phenobarbitone between divided daily doses of regular phenobarbitone and phenobarbitone in spansule form, when equal doses of the active drug were given For a drug which is excreted as slowly as phenobarbitone blood-concentration variations are slight, and it remains to be proven that they are of clinical importance

If the missing control experiment were carried out it might be possible to show how worth-while economies could be made in the country's drug bill

MITRAL VALVOTOMY AND PREGNANCY

Sir,—In his comments on our paper of March 15, Dr Richard Turner (April 5) states that "surgery during pregnancy is undesirable unless the evidence for tight [mitral] stenosis is based on severity of symptoms before pregnancy began" We think this goes too far, for we believe that Dr Turner underestimates the risk to life when a patient with mitral stenosis develops severe symptoms for the first time *during* pregnancy Although we agree that pregnancy may magnify the symptoms of mitral stenosis, we believe that valvotomy should be undertaken in at least some of these cases because

1 The risk of valvotomy during pregnancy is relatively reasonable (2 deaths in 97 cases)

2 The mortality is very high if pulmonary œdema develops during pregnancy (about 40%, unpublished data) and death does not usually occur in the first attack

3 When pulmonary œdema has occurred in pregnancy, a further pregnancy is too dangerous unless valvotomy is undertaken

Valvotomy (like termination of pregnancy) should not be undertaken until the cardiac condition has been adequately treated medically

We are surprised that Dr Turner demands "objective signs of long-standing pulmonary hypertension" and "an electrocardiographic pattern of right ventricular hypertrophy" before advising surgery In our experience such evidence is present in only about a third of patients with tight mitral stenosis, and the majority of these patients are so incapacitated that pregnancy is uncommon

TESTING OF STERILISATION METHODS

Sir,—Much misgiving has arisen on the value of testing sterilisation procedures by the use of heat-resistant spores It is quite easy to isolate from soil and dust aerobic-sporing bacilli which are able to stand up to a great deal of heat, but in our experience the spores rapidly lose this property on subculture For instance, an aerobic-sporing bacillus isolated from soil resisted being heated in a boiling-water bath for $1^1/_2$ hours, but a subculture of the same organism was destroyed in less than 2 minutes in the same water bath

The "test spores" issued by the Southern Group Laboratory until recently are killed in 7 minutes at 100°C Preliminary work by one of us (E H B) has shown that the survival power of spores is dependent on the method of preparing them, and in particular on their water content. Cultures incorporated in linen discs and then freeze-dried are much more resistant to heat than those dried by evaporation in warm air The freeze-dried preparations have been tested by placing a disc in a capped $^1/_2$ oz MacCartney bottle and not in an envelope This produces as closely as possible a "standard" preparation in a "standard" air-pocket, and under these conditions the discs have proved satisfactory

Conditions	Maximum internal temperature	*Bacillus subtilis* freeze dried	*B subtilis* evaporated	Browne's tubes yellow	Browne's tubes black	Browne's tubes green
Steam 30 min at 109°C or 5 lb per sq in	110 C	Not killed	Killed	Amber	Amber	
Steam 15 min at 115 C or 10 lb per sq in.	115 C	Killed	Killed	Green	Nearly green	
Steam 20 min. at 115 C or 10 lb per sq in.	116°C	Killed	Killed	Green	Green	
Hot air 60 min. at 160 C	160 C	Killed	Killed			Green

Because of the difficulty of obtaining, and maintaining, a "standard" test strain some pathologists have been relying on Browne's tube, which are supplied in the following forms

For glove sterilisation	yellow spot
For dressing sterilisation	black spot
For hot-air sterilisation	green spot

According to Medical Research Council memorandum no 15 (1955), gloves are satisfactorily sterilised at 109 C or 5 lb per sq in pressure for 30–40 min Unfortunately, the indicator in Browne's glove tube (yellow spot) will not satisfy these requirements, in that the colour change is often not amber, and certainly not green Heating to 115°C or 10 lb per sq in pressure for 15 min satisfactorily converts the red colour to green This treatment does not damage rubber gloves, and their normal life will not be diminished by this repeated steam treatment [1]

From the accompanying table it can be seen that freeze-dried spores resist 109°C or 5 lb per sq in pressure for 30 min., but are killed at 115°C or 10 lb per sq in pressure for 15 min, whereas the evaporated spores are killed in both cases

We cannot, therefore, rely on the present "sterility test packets" Freeze-dried discs will in future be issued for pathologists to transfer into MacCartney bottles

ARTIFICIAL RESPIRATION WITH THE TUNNICLIFFE BREATHING-JACKET

SIR,—I read with great interest Dr Spalding's and Dr Opie's thorough report (March 22) on the Tunnicliffe breathing-jacket. In principle the jacket has seemed an advance on the cuirasse, as they have pointed out However, since it is more complicated to fit on the patient than the cuirasse, we have only tried it for respiration of three patients who were expected to need more ventilation than the Monaghan or ' Spirashell ' cuirasse would provide On these patients its performance has not come up to expectations

For the first of these, a boy aged 6 years, the smaller size of jacket proved too bulky On the second, a man with a collapsed left lower lobe and with a vital capacity of 50 c cm , it would only produce a tidal air of 190 c cm with a pressure of —27 cm of water Its performance on the third patient, a woman with a collapsed left lower lobe and a vital capacity of 90 c cm , was studied more fully, and the following figures were obtained (the tidal air was measured on a special small-volume-recording spirometer).

	Positive-pressure machine	*Tunnicliffe jacket*		*Spirashell cuirasse*	
Pressure (cm water)	+15	—27	—17	—27	—17
Tidal air (c cm)	410	350	220	350	250

A small or larger jacket produced lower figures

Although the Tunnicliffe jacket provided no better ventilation than the spirashell cuirasse, it was preferred by this patient because it was more comfortable, though it restricted arm movements

These two adult patients were more difficult to ventilate than usual This was shown by the relatively high pressure needed for correct ventilation by the positive-pressure machine In such cases we expected that the Tunnicliffe jacket might prove invaluable The figures above show that this was not so

R V WALLEY

LUNG RESECTION FOR BRONCHIECTASIS

SIR,—I agree with Mr Shaw (April 5) that your annotation of March 22 gives an unjustifiably gloomy picture of the modern results of resection for bronchiectasis Surely it is wrong to quote one small series alone as confirmation of the view you had stated previously, when the results of this series, for one reason or another, appear to be greatly inferior to those published by the many other workers in recent years Certainly lobectomy would seldom be justified if the risks were as great as you suggest, but in fact the operative mortality is probably considerably less than 1% in the best hands

New bronchiectasis developed in a third of the patients This is a very high proportion, but the statement means little unless one knows the degree and type of bronchial dilatation, and the severity of the associated infection and symptoms as compared with those present before operation

It is generally agreed that resection is often followed by some loss of lung function on the same side, but Long et al[3] showed that this may be compensated for by an increase in function of the other lung and that there may in fact be an increase in the maximum breathing capacity The mechanical and anatomical changes following resection may be harmful, but possibly not more so than the continued presence of a reservoir of infection with its tendency to local and occasionally distal spread

The indications for or against surgery in a particular case are sometimes clear cut, but in many a decision is difficult, not because the results of surgery are bad but because *the results* of both surgery and medical treatment are good

One of the reasons why it is so difficult to make broad generalisations about the relative merits of the two methods of treatment is that there are few if any published results of long-term medical treatment which can be compared fairly with the many surgical reports

I suggest, Sir, that an open mind should be kept on this difficult subject and that there is no good evidence on which to condemn resection for bronchiectasis

The Marsden Hospital, Burnley

W H HELM

ADRENOCORTICAL STEROIDS IN MALIGNANT EXOPHTHALMOS

SIR,—We wish to support the plea by Dr Hoffenberg and Dr Jackson (March 29) for a further therapeutic trial of adrenocortical steroids in malignant exophthalmos We are prompted to report our experience with a recent patient

In May, 1956, a woman, aged 23, had a subtotal thyroidectomy For the previous seven years she had been increasingly nervous, had noticed excessive perspiration, and had lost 7 lb in weight In spite of these symptoms, she preferred hot weather Following the operation, the nervousness was only slightly improved, and she failed to gain weight

Slight protrusion of the right eye was first noticed four months before her operation, but later this became more severe, and in October, 1956, a right tarsorrhaphy was performed Her condition then remained unchanged until November, 1957 She then developed severe continuous frontal headache and pain behind both eyes The protrusion of the right eye became much more severe, and the left eye also began to protrude There was a rapid deterioration in vision in both eyes, especially in the right eye

On admission to the National Hospital on Nov 21, she had bilateral exophthalmos, more on the right, but no chemosis or conjunctival œdema Her visual acuity was reduced to counting fingers in the right eye, and to Jaeger (J) 20 in the left The visual field was full on the left, but the lower half of the right visual field was lost The right pupil did not react directly to light Bilateral early papillœdema was present There was severe restriction of bilateral upward gaze, and of abduction of the right eye Although she was nervous, there were no signs of thyrotoxicosis

She was treated immediately with prednisolone 10 mg t d s and triiodothyronine 10 μg t d s Because of the lack of improvement, a right orbital decompression was performed on Nov 23 This unfortunately failed to save the vision of the right eye, which became totally blind The left eye, however, dramatically improved, and by Dec 2 her visual acuity had increased from J20 to J2, the papillœdema had subsided, and her external ocular movements were full Thyroid gr ½ b d was substituted for the triiodothyronine, and she was discharged on this drug and on prednisolone 10 mg t d s

As an outpatient, she continued to take thyroid gr ½ *b d* but the dosage of prednisolone was progressively reduced to 5 mg daily over a period of one month The drug was completely withdrawn on Feb 26 Five days later, she developed mistiness of vision of the left eye, and two days later this became much more severe She was readmitted on March 5 There had been a considerable increase in the degree of proptosis of the left eye, and her visual acuity was reduced to J10 There was complete loss of the temporal half-field, and the defect also spread to involve most of the lower nasal quadrant The external ocular movements were full, and the left disc was

---

2 Alder, V E , Gillespie, W A *J clin Path* 1957, 10, 299

3 Long J H , Norris, C M , Burnett, W E , Wester, M R *J thorac Surg* 1950, 19, 477

normal The right eye was blind, with optic atrophy and a fixed dilated pupil

She was immediately started on prednisone 20 mg t d s, and within thirty-six hours there was much improvement The visual field defect began to shrink, and the visual acuity increased By March 11, her visual acuity had become normal (J1), and only a minimal peripheral temporal field defect remained This defect has since disappeared She has continued to take thyroid gr $^{1}/_{2}$ b d, but the dosage of prednisone has now been reduced to 10 mg t d s

This case has proved instructive Although decompression failed to save the sight of the right eye, the left eye improved after operation and this may have been due to the prednisolone which was being concurrently given The relapse of the left eye followed five days after stopping prednisolone, and impressive improvement began within thirty-six hours of resuming steroid treatment Although no firm conclusions can be drawn from a single case, we feel that it is reasonable to attribute this patient's improvement to steroids, at any rate we do not propose to risk withdrawing treatment a second time

We wish to thank Dr Denis Brinton for permission to report this case

The National Hospital for Nervous Diseases,
London, W C 1

R W HORNABROOK
J C LEONARD

PRE-ECLAMPTIC TOXÆMIA

SIR,—Dr Margaret Robinson (Jan 25) holds that the ingestion of extra sodium chloride in the diet is successful in the prevention of toxæmia of pregnancy, but I believe that her study has many shortcomings Because of the large circulation which *The Lancet* has to the medical profession of this country, I think that this article is more damaging to prospective mothers and to the information of those concerned with their care than any other piece of literature presented to the obstetrician in the past thirty years

We have statistically analysed Dr Robinson's data We found that they were statistically significant in the overall groups In the age-groups 0–30 and 30–50, the data were significant where toxæmia was commoner among those on salt-poor diets The data were significant as regards parity only up to para 4 but were not significant beyond this parity The neonatal deaths and the presence of œdema showed statistical significance On the other hand, there was no statistically significant correlation among the prenatal deaths, antenatal bleeding, and antepartum hæmorrhage We could not differentiate between antenatal bleeding and antepartum hæmorrhage

Although statistically significant differences existed between the low-salt and the high-salt group, this does not necessarily mean that the patient was protected against toxæmia because of the high-salt diet just because 70% of the patients on the high-salt diet did not develop a toxæmia according to the definition given in the paper Some other comparisons might be drawn relative to toxæmia of pregnancy too

Chesley (personal communication) has shown that there is a statistically significant correlation between the presence of toxæmia of pregnancy and membership of the Baptist Church We have been able to show a high incidence of toxæmia of pregnancy in underweight patients—but also in those who are overweight It thus seems that some other variable existed as a third factor in the group of patients reported by Dr Robinson In England, where there still exist difficulties in getting satisfactory nutrients, why could not the variable of nutrition account for the differences noted in her series? Also, it is not known whether her patients on the increased salt intake were not in various degrees of salt depletion before the administration of supplemental sodium chloride It seems as though there was no actual control over the sodium-chloride intake among these patients, they were merely instructed to increase their salt intake It might be open to some question whether the patients actually complied with the advice offered, and even if they did comply by increasing their intake, they may conceivably have increased it only to a level that would be reached by another group who reduced their sodium-chloride intake

Even under the strictest metabolic conditions of study in hospital patients, there are difficulties in controlling compliance with rigid regimes The study was not controlled in a hospital, nor were there any biochemical, weight, or endocrinological investigations

Seattle 5, Washington

RUSSELL R DE ALVAREZ

CARDIAC SYNCOPE AFTER SWALLOWING

SIR,—Concerning Dr James' interesting paper last week, may I just mention, for the sake of completeness, a case of a similar syndrome which was published by myself and H Uiberall[1]

A lady, aged 62, had a characteristic Stokes-Adams syndrome with unconsciousness, after swallowing food or fluids first thing in the morning The electrocardiogram showed signs of sinus bradycardia and ventricular extrasystoles During the attack, the pulse-rate dropped from about 80 to 44 and the blood-pressure from 220/100 to below 80/0 mm Hg The attacks began soon after a bout of tonsillitis At the time of the hospital investigation it was possible to produce an attack by touching the left posterior arch of the soft palate After a severe attack there was a refractory phase for over an hour which could be used for the intake of large amounts of food without provoking further attacks The left tonsillar region was anæsthetised and radium 100 mg implanted for 3 hours The attacks increased in intensity for the next 2 or 3 days On the 7th day a second application of radium was carried out with renewed intensity of attacks lasting about 7 days From the 8th day onwards after a second insertion of radium the attacks disappeared, and the patient remained free from attacks for the next $9^{1}/_{2}$ months

London, S W 1

V C MEDVEI

INDIRECT BILIRUBINÆMIA

SIR,—The observation by Danoff et al (*Science*, April 4, *Lancet*, Feb 8, p 316) that glucuronic acid and its sodium salt administered to infants with hyperbilirubinæmia resulted in a striking but transient fall in unconjugated bilirubin is of extreme interest to all pædiatricians In our work with glucuronic acid we have been unable as yet to demonstrate a significant fall in bilirubin level However, we wish to call attention to the potential hazard in the use of these preparations in view of the fact that physicians may be tempted to substitute glucuronic-acid therapy for replacement transfusions in newborns with dangerously high serum-bilirubin levels Should the reported findings be confirmed, there is no indication regarding the fate of the declining serum-bilirubin The possibility has not been excluded that bilirubin is driven from the blood into the tissues, thus increasing the risk of brain damage

Until further investigative work determines the exact pharmacodynamic action of these compounds we feel strongly that physicians should refrain from using them in the newborn

THE DOCTOR'S ATTITUDE TO HIS PATIENT

SIR,—Because Dr Ryle (April 12) is the fortunate possessor of such characteristics that he can adequately treat his patients he should not decry the endeavours of us others to understand our patients better, or deny that we others do need to suffer a change before that can happen

I am sure "we" are in the majority otherwise, would there be so many "doctor satellites" revolving, as hopelessly as "Laika", around our surgeries?

We all suffer a "sea-change" in the depths of our personalities by constant contact with those around us, but the change into something richer and more understanding is quicker in the greater awareness of a seminar such as Dr Michael Balint's

Dr Ryle and Dr Tuckman (March 29) have evidently had no such experience For my own I shall always be grateful

Ilford, Essex R N COMPTON SMITH

A SLIDE-HOLDER FOR STANDARD FILING CABINETS

SIR,—The problem of storing a large number of lantern slides or dental radiographs compactly and yet in a way which makes them readily available for inspection and selection may be solved by the construction of slide-holders in the following way

Strips of transparent polyvinyl chloride (P V C) ($1^3/_4$ in × $14^1/_2$ in) are welded on to a sheet of natural P V C ($10^1/_2$ in × $14^1/_2$ in) to form twenty-four pockets, each holding one 2 in × 2 in slide (fig 1) Welding is by radio frequency

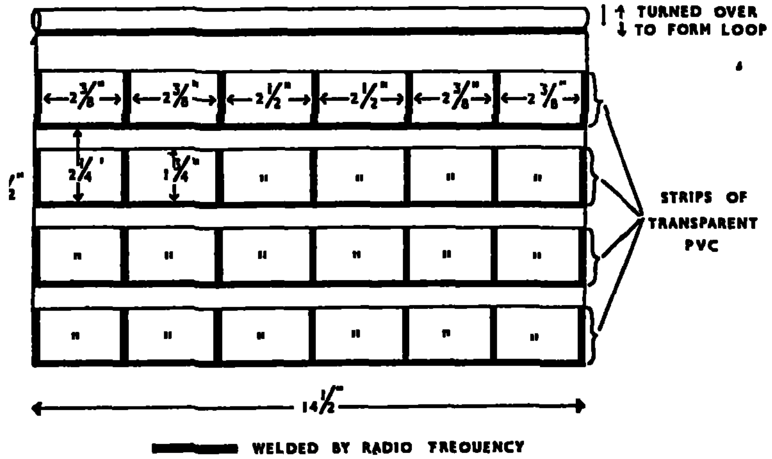

Fig 1—Dimensions of slide-holder

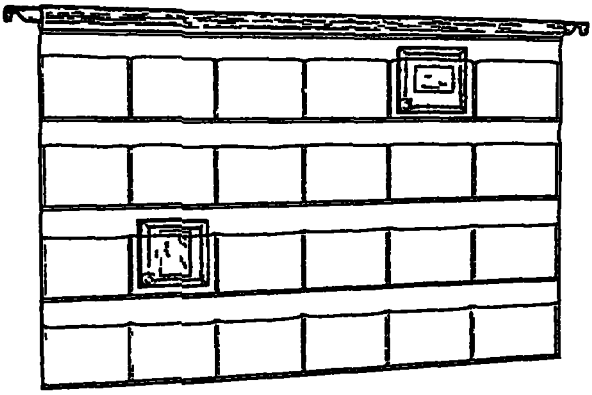

Fig 2—Slide-holder complete

At the top of the frame a loop is made to hold a standard filing-cabinet metal bar (fig 2) The frame can then be placed in a filing-cabinet drawer, each drawer holding about 100 frames, or 2400 slides For catalogue marking or indexing a typed card can be slid in the loop holding the metal bar, typescript can be seen through the translucent P V C

All the slides in a frame may be viewed by holding the frame up to window light (the P V C diffuses the light giving a standard illumination), or by hanging in front of a standard X ray viewing-box

For transport of slides the metal at the top of frame can be withdrawn, the whole plastic framework can then be folded into a neat package and carried in the pocket The materials to make one such holder cost about 1*s* 6*d*

Holders can be made similarly to take $3^1/_4$ in × $3^1/_4$ in slides, dental radiographs, or photographic transparencies For demonstration purposes larger holders can be made to cover the whole of a viewing-box screen

Sheets of P V C were supplied by Commercial Plastics, and strips ('Vybak') by Bakelite Ltd

Department of Surgery,
University of Durham J E ROGERS

BLEEDING ULCER IN A MECKEL'S DIVERTICULUM

SIR,—Complications arise in 11% of cases of Meckel's diverticulum—intestinal obstruction, diverticulitis, and peptic ulceration with hæmorrhage or perforation

Lecène[1] says that peptic ulcers of Meckel's diverticulum are constantly to be found where the mucosa of the small intestine meets an islet of ectopic gastric mucosa—usually at the base of the diverticulum This leads to the accepted hypothesis that the peptic activity of this ectopic mucosa produces autodigestion and ulceration of the intestinal mucosa This concept allows a distinction between ulcers due to inflammation and those due to mechanical causes such as intussusception of the diverticulum

Intestinal bleeding from these ulcers is usually slight, but sometimes it may be severe, appearing in the stool as red blood and recent clots, and endangering the patient's life

A boy, aged 2 years, had been in hospital three times in 1955, for whooping-cough, gastrointestinal disorders with generalised urticaria, and an unidentified fever He had passed some ascarids in the stool On Nov 23, 1956, he suddenly became intensely pale, giddy, and cold His temperature went up to 102 8°F (39 3°C) and next morning he passed a stool almost entirely composed of fresh blood, about 600 ml At 3 P M we noted intense pallor of mucous membranes and skin (pulse 140 a minute, blood-pressure 80/60 mm Hg) There was peri umbilical tenderness, and the abdomen was slightly distended, with transient and local muscular guarding below the umbilicus No mass could be felt or seen in the rectum, but the exploring finger was stained by fresh blood An abdominal radiograph showed gas in the intestines without fluid levels Hæmoglobin 57%, red cells 2 72 million per c mm, clotting-time 8 min, bleeding-time 3 min

The presumptive diagnosis was bleeding from an ulcer in a diverticulum, and operation was undertaken on Nov 24 300 ml of whole blood was transfused during the operation and another 300 ml postoperatively The small bowel was slightly congested and distended by gas The large bowel was dark purple and full of blood About 30 cm from the ileocæcal junction was a Meckel's diverticulum on the antimesenteric border Its tip was congested and contained a tumour the size of a lentil Very many ascarids could be felt in the small ntestine The diverticulum was removed and its stump nvaginated without narrowing the lumen of the ileum

---

[1] Lecène, cited by Forgue, E. *Précis de pathologie externe*, vol II, p 676 Paris, 1939

The postoperative course was complicated by persistent paralytic ileus, with abdominal distension and vomiting, which subsided only after continuous gastric suction for 48 hours An enema returned black blood and clots in great quantity Intravenous fluids were given On Nov 26 the Hb was 72%, and 600 ml blood was transfused On the third postoperative day the child was allowed out of bed, and on Dec. 5 he was discharged

The diverticulum was 4 cm long, and 1 3 cm wide at the base The mucosa was generally of the small-intestine type, but at the tip of the diverticulum was an islet of gastric mucosa Just near this was an ulcer, smaller than the ectopic tissue, not very deep, covered with a clot of blood Microscopic examination of the specimen (Dr H Breazu, Ploesti) showed at this level a deep layer of tubular glands of gastric type

The diagnosis was difficult in that the patient had had no previous alimentary-tract hæmorrhages, the illness started with fever, X-ray examination was inconclusive, and there was no umbilical anomaly to point to a diverticulum

The ulcer is usually situated near the point where the mucosa of the ileum joins that of the diverticulum, but in this case this region was normal An ulcer at the tip of the diverticulum is very rare, and we have found only one report of such a case [2]

When one of these ulcers bleeds, operation is always necessary, for death may be caused by continued hæmorrhage into the gut, perforation followed by generalised peritonitis, or ulceration of the mesodiverticulum with intraperitoneal hæmorrhage [3]

Rumania

CONSTANTIN CEPLEANU
ION TUTICA

HOOKWORM AND ANÆMIA

SIR,—The association between hookworm infestation and iron-deficiency anæmia is almost traditional Bilharz first described hookworm in Egypt in 1851 Three years later his pupil Griesinger [4] linked hookworm infestation with the disease called Egyptian chlorosis Ashford's [5] description (1900) of patients in Puerto Rico with severe anæmia and heavy infestation with the worms received wide recognition Thereafter ancylostomiasis was regularly added to the list of causes of iron deficiency in standard textbooks of medicine

Loss of blood at the site of attachment of the worms was generally thought to be the immediate cause of the anæmia But in recent years some serious doubts have been expressed The load of worms, as judged by the ova count in the fæces, rarely correlates with the severity of the anæmia Furthermore patients with an apparently heavy infestation are not always anæmic The suspicion has grown that the association between hookworm and anæmia is fortuitous, since people infested with the worm commonly live on diets composed chiefly of cereals, poor in proteins, calcium, and ascorbic acid On such a diet defective absorption of iron would be expected Foy and Kondi [6]—two hæmatologists with wide experience in the tropics—have summarised present views as follows "The consensus of opinion then is that hookworms are not a common càuse of anæmia, but until more critical work has been done it is better to leave the question open "

At this moment of uncertainty we wish to draw attention to the original observations of Boycott and Haldane,[7] who investigated the cause of severe anæmia among tin-miners in Cornwall This had been attributed to bad air, but this explanation they quickly put out of court Boycott and Haldane found that the men were heavily infested with *Ancylostoma duodenale*, the larvæ of which penetrated their clothing soaked in mine water Some of the men had less than 40% of hæmoglobin Such a degree of anæmia in an adult male could not possibly be attributed to any defect in the common British diet of that time

Boycott and Haldane added a remarkable observation Using the carbon-monoxide method for measuring blood-volume, developed in Edinburgh by Haldane and Lorrain Smith,[8] they showed that in some of the anæmic Cornish miners the blood-volume was increased, so that the anæmia was due to hæmodilution rather than to loss of blood from the gastrointestinal tract

We suggest that a properly financed research project into the association between hookworm and anæmia is now overdue

ESSENTIAL FATTY ACIDS, LIPID METABOLISM, AND ATHEROSCLEROSIS

SIR,—In *The Lancet* of April 5 Dr Keys takes exception to statements contained in our paper which appeared on Feb 15 If we have misquoted Dr Keys, we are very sorry indeed I should, however, like to point out that, in the field of dietary fats, it is very difficult *not* to misquote Dr Keys, inasmuch as his concepts and statements have differed very radically from one year to the next Perhaps this is to some degree unavoidable in a field in which knowledge is progressing very rapidly We should, however, like to suggest that the presentation of precise mathematical formulations that enable one to predict precisely that John Smith's cholesterol level will be precisely so much, in response to precisely so much saturated and unsaturated fat, is very premature indeed As noted in our paper of Feb 15, not only the relative but the absolute amount of polyunsaturated fat required to produce a given fall in the level of cholesterol and other plasma-lipids varies markedly with the age of the patient, and the presence of known atherosclerosis Older individuals with obvious vascular disease may for a time require complete removal of saturated fat from the diet and the administration of large amounts of linoleic-acid-containing fat, in order to obtain a significant and maintained fall in lipids Young normal individuals may respond to quite modest amounts of polyunsaturated fats in the presence of appreciable amounts of saturated fat

We can agree in part with Dr Keys' present thoughts —that is, those of his thoughts stated in his letter in the April 5 issue of *The Lancet*—regarding the relatively "neutral" properties of oleic acid as compared to carbohydrate, if one considers only the effects upon plasma-cholesterol levels However, the effects upon plasma-triglyceride are very different, inasmuch as, at least in our experience, there is a very marked rise in plasma-triglyceride when carbohydrate is substituted for any type of fat in the diet. This is not observed when highly purified ethyl oleate is administered Conceivably, the

elevated triglyceride level with high carbohydrate feeding is in some way related to marked acceleration of lipogenesis

A final comment concerning "essential-fatty-acid deficiency" an essential nutrient, by definition, is one which cannot be synthesised in the body in adequate amount If it is not supplied in the diet, its absence will eventually be associated with abnormalities of structure and/or function Linoleic acid appears to fulfil the requirements of this definition The fact that, in abnormal individuals, relatively large quantities are required to produce the desired metabolic effects seems to us beside the point, insofar as "essentiality" is concerned When we have a solid understanding of the way in which linoleic acid lowers plasma-lipid levels, we will be in a much better position to talk of physiologic *versus* pharmacologic effects

ABSENCE FROM WORK ON A MEDICAL CERTIFICATE

SIR,—Dr Ashworth (April 5) must be given the benefit of the doubt in case he is really trailing his coat However, he reports the case of the father of two sick children whose wife is working in fear of dismissal, in which it seems indefensible to issue a National Insurance medical certificate

Humanity should be satisfied, by all means, by giving a note for the respective employer of father or mother stating that their children are ill and require the attention of a parent, but to confuse humanity with "expeditiousness" seems wrong

To advocate this wide interpretation of sickness certification, whilst expedient, will in fact discredit the National Health Service further (or rather the general practitioner) and substantiate the employers' mistrust of medical certificates Such interpretation will encourage all the other parents, who as yet are too self-respecting, to follow this example at the next opportunity

Sickness benefit for a parent is not to be confused with payment for parental duties The statement which the doctor signs on form Med 1 is that his patient is incapable of work

The specious argument—that 5% or 3% of £840 million is a negligible sum, which can be ignored and is cheap at the price for wrongful application of sickness benefits—holds no water There are many necessary improvements in the Health Service which could be carried out if this sum were available

Edinburgh

E V KUENSSBERG

SIR,—Many of us will have been given food for thought by Dr Ashworth's excellent article One is relieved to see the relative smallness of unjust claims, and this is probably easily offset by those who work when, by all the rules, they should be in bed (though most of us could say from experience that this has surprisingly few ill-effects)

Unless there is clear evidence to the contrary, one has to accept that the patient is giving the facts as he knows them To start on the assumption that one is being misled, as I suppose a professional referee has to do, would make life impossible, and, anyway, in self-defence one has to play for safety A patient who collapses with pneumonia or coronary disease after being sent off to work lends no credit to the profession, nor is the man who has to be sent home with a temperature after seeing his doctor on the way to work when his temperature was normal As Dr Ashworth says, one may have to observe a patient for a time before making a firm decision

Arising from this I should like to raise another issue It seems to me impossible to give an honest note in a large proportion of requests for a day or two's absence If pressed, one could write a full report in which the pros and cons could be stated, and for which the proper fee would be charged While giving what is in effect a duplicate of a "panel" note for, say, 2*s*, is a reasonable proposition and a convenience to employer and employee, to certify for 2*s* that a man is unfit to work today but will be recovered from his lumbago tomorrow is a convenience only to the dishonest By this means a man can blackmail his employer—who may well know that he was at a football match—into paying him a bonus This policy has brought certification into contempt both by employer and employee, as I well know from speaking to both "Anyone", they say, "can get time off if they pay their doctor 2*s*"

I believe that employers would get less absenteeism if they relied upon a written statement from the worker—the majority of whom are honest—and it would save the genuine patient the inconvenience of waiting in the surgery It would save the drug-bill the cost of innumerable bottles of medicine which one feels bound to give to relieve symptoms in patients one has decided are not fit for work, and I am sure it would improve the status of doctors if they did not show themselves so ready to be deceived I know that this has been debated more than once by the B M A, but on the grounds I have given I would appeal for a discontinuation of the practice of what is in effect, though not intent, misleading certification

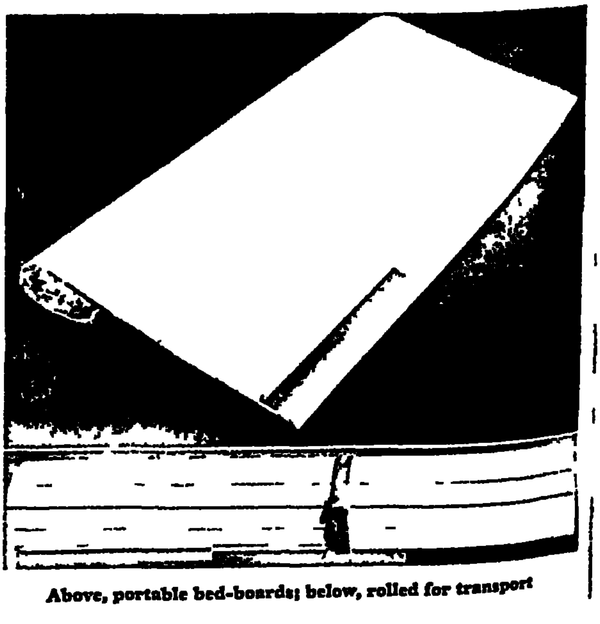
Warwickshire

W BRIAN GOUGH

PORTABLE BED-BOARDS

SIR,—Thousands of people with backache, due to intervertebral-disc and other lesions, now prefer to sleep on hard beds These people must avoid the well-sprung mattress Holidays and visits away from home are spoiled by backache through sleeping in comfort

I have had made for me what might be described as a small tap-mat—made of hard wood and backed with canvas This can be rolled up, put in a car, and carried round with ease—then laid under a mattress When rolled



Above, portable bed-boards; below, rolled for transport it measures only 6 in in diameter It has proved a great success

It was made for me by Messrs Capes, of Sutton Lane, London W 4 Mr Cape too has backache, so he took a special interest and now has one for himself

London, S W 7

O S THOMPSON

MODIFIED TRACHEOTOMY TUBE

SIR,—I was most interested to read Dr Napier's letter of April 5

Unfortunately he did not illustrate his tube,[1] which he described as "a skeleton tube with open back" It would seem that its main purpose was to facilitate the "weaning" of the child back to normal breathing

I feel that Dr Napier has perhaps not fully appreciated the reason for the modifications I describe (March 15) There are in fact several modifications, all equally essential to enable it to perform its function The tube is designed to facilitate coughing in the acute stages of respiratory infection, such as tracheobronchitis and bronchopneumonia or in chest injuries It also allows for inflation of the lungs following suction, the use of controlled ventilation should it be required, and the induction of anæsthesia if bronchscopy is necessary

Alder Hey Children s Hospital,
West Derby, Liverpool

FRANK WILSON

LONG-TERM ANTICOAGULANT TREATMENT FOR CORONARY-ARTERY DISEASE

SIR,—In Dr Hougie's letter last week I am sure a misprint has occurred "There is no evidence that there is present in normal plasma a factor which can restore the prolonged bleeding-time of patients with von Willebrand's disease to normal" should surely read "There *is* evidence " Most probably Dr Hougie is referring to the factor already described by Nilsson et al.[2]

P WOLF

*** We are grateful to Dr Wolf for drawing attention to our mistake in reproducing Dr Hougie's "There is *now* evidence " as "There is *no* evidence "—ED L

PENICILLAMINE AND DIMERCAPROL

SIR,—In his article entitled Penicillamine, a New Oral Therapy for Wilson's Disease, Dr J M Walshe[3] writes

> "A new form of oral treatment with dimethyl cysteine (penicillamine) is described. Given in doses varying from 0 5 to 1 5gm. daily to six patients with Wilson s disease, it provoked a very large increase in the urine excretion of copper, in five patients it proved more active than BAL in this respect."

Citing Dr Walshe's article, the statement is often made (e g, by Dr Boulding and Mr Baker[4]), that penicillamine "appears to be more efficacious than dimercaprol"

If two drugs are to be quantitatively compared, equimolar amounts should be given using the same vehicle and the same route of administration, but in Dr Walshe's studies the penicillamine was given orally by capsule while dimercaprol was administered intramuscularly and probably dissolved in oil

In a forthcoming article[5] dealing with the ability of penicillamine to protect rats against the lethal effects of mercuric chloride, I present evidence indicating that when equimolar amounts of dimercaprol, *dl*-penicillamine, or *d*-penicillamine dissolved in saline are tested intramuscularly, dimercaprol is definitely superior to *dl*-penicillamine and only slightly superior to *d*-penicillamine under the conditions of our experiments It would be of interest to compare equimolar amounts of penicillamine and dimercaprol, administered by the same route and in the same vehicle, to determine the relative activities of these drugs on the excretion of copper

More Radioactivity in Britain

Kodak Ltd make daily measurements of London radioactivity to safeguard their photographic manufacturing processes, and they detected an increase in late March[1] The activity reached a peak on March 24, when it was 10–20 times normal (it was 100 times the normal after the Windscale accident) The Atomic Energy Authority[2] has since confirmed that there was a "small but sharp" temporary increase in radioactivity over Britain during the second half of March It is assumed that the increase was due to the recent series of bomb tests in the Soviet Union, and was caused mainly by short-lived fission products The Authority is to keep a careful watch in the coming months for the longer-lived and more dangerous products

Tuberculosis and Cancer in 1957

IN England and Wales last year the death-rate from tuberculosis and the maternal mortality-rate both reached new low records There were 4250 deaths from respiratory and 534 from other tuberculosis, giving rates per million of 95 and 12 respectively Since 1947 the death-rate from respiratory tuberculosis has fallen by 79% The maternal mortality-rate per 1000 live and still births was 0 47 (0 39 excluding abortions) There were 349 deaths from maternal causes (excluding abortion) compared with 399 the year before These are provisional figures[3]

The death-rates from cancer were 2312 per million for men and 1891 for women, the figures for 1956 were 2274 and 1891 About 33% of the male and 6% of the female cancer deaths were from lung cancer, and the death-rates from this disease increased from 726 per million in 1956 to 759 for men, and from 111 to 116 for women.

Obituary

JAMES DRUMMOND GRAHAM

Kt, C B, C I E, M B Glasg, D T M

Major-General Sir James Graham, formerly public-health commissioner with the Government of India, died on April 4 at the age of 83

Having been resident physician at the Glasgow Royal Infirmary, he entered the I M S in 1900, and saw military service in Waziristan Before the first world war, with an appointment in the United Provinces, he was doing valuable work on malaria, showing a decided aptitude for medical research he was one of a number of senior officers who, under a planned scheme, were making the first malaria survey of all India For the eight years 1915-23, however, he was away from India—first on the staff of the Egyptian and Mesopotamian expeditionary forces, and later, from 1920, as director-general and inspector-general of the Iraq health services and adviser to the Ministry of Public Health On his return he became public-health commissioner with the Government of India, and in 1932 he officiated for some months as director-general, I M S In his post as commissioner, writes S R C, "he excelled as an administrator Whilst public-health administration in India was the direct responsibility of Provincial Governments, overruling control of public health and medical research lay with the Central Government, and Sir James Graham played a vital part in development of public health and medical research organisation in India He was, moreover, no remote and inaccessible official He worked quietly and understandably in friendly consultation, always helpful and encouraging He was I think liked by everybody for his friendly simplicity and kindness There was something very straight and fresh about Graham and one was always stimulated by him As a Lowland Scot (he came from Ayrshire) he had a streak of canniness in his make-up, but this did not affect his giving ungrudging help and encouragement at all times to the schemes of others"

Internationally he was known to many as delegate for British India in the Office Internationale d'Hygiène Publique, a member for some years of the Health Committee of the League of Nations, and chairman of the advisory committee of the League's eastern health bureau at Singapore He was appointed C I E in 1919 and C B in 1931, and was knighted in 1934, the year of his retirement

J M writes of his "old and greatly valued friend" "His record of services shows that he was selected for a succession of important appointments demanding exceptional qualifications The many honours conferred on him testify to the conspicuous success with which he filled all these posts This was due not only to his great professional qualifications but also to his personality, which made him universally popular with his colleagues and others with whom he came into contact, irrespective of race or nationality It was by no means a case of his being 'hail fellow, well met!' but of his natural friendliness of disposition and his cosmopolitan outlook on life"

He married in 1912 a daughter of Colonel C Seymour, A M S, and they had one son In later life Sir James and Lady Graham lived for some years in a country house in the south of France Progressive failure of his eyesight made reading and writing difficult, but did not prevent his corresponding with his friends from Indian days

Notes and News

A NATIONAL LIBRARY OF MEDICINE?

A MEMORANDUM prepared by the medical section of the Library Association expresses concern at the decision to omit clinical medicine from the coverage proposed for the National Lending Library for Science and Technology The need for a national library of medicine, the Association points out, has been felt for many years, for the two largest general medical libraries in this country—those of the Royal Society of Medicine and the British Medical Association—exist to serve their members and have had to reduce the help they used to give other libraries A national medical library service is needed particularly by the research-worker with non-medical qualifications

Individual medical schools, postgraduate institutions, and research organisations cannot hope to provide and house libraries sufficiently wide in scope to satisfy from their own resources all the potential needs of their users Inter-library lending has increasingly become an unsatisfactory answer to the problem of meeting those wide needs

Moreover the ever-increasing volume of "medical" literature, the increasing variety of forms of publication (to the monograph and journal must now be added the symposium, the research conference proceedings, the project report, the transcript of a tape-recording, and so on), and the diversity of sources from which *one form or other of publication comes, demand a correspondingly greater effort for their tracing* and acquisition The individual working library cannot provide that effort It is better that each should, whilst maintaining a search and acquisition service adequate for its regular needs, be able to turn to a central source

There appear to be two practicable solutions to the problem of providing a national service of medical literature

1 A National Library of Medicine could be built on an existing comprehensive medical library

2 The scope of the new National Lending Library of Science and Technology could be widened to include medicine in its broadest aspects

The Library Association recommends a thorough examination of the possibility of creating a National Library of Medicine based on the present collections of the Royal Society of Medicine, cooperating and discussing policy with the National Lending Library of Science, as at present envisaged, and making its services available on the same lines If this proves impossible, the Department of Scientific and Industrial Research should consider covering the whole field of medicine in its broadest aspects by the National Lending Library of Science and Technology

TUBERCULOSIS IN THAILAND

IN Thailand, which has some 18 million inhabitants, a tuberculosis service was established by the Thai Government late in 1949, and a central chest clinic—the first of its kind in the country—was set up in the heart of Bangkok In 1951 the World Health Organisation and UNICEF gave active assistance through the W H O tuberculosis control project, described in our columns by the late Dr Benatt[1] who became its director This project was limited to two years, but much of its work has been continued The central chest clinic has now become the tuberculosis demonstration and training centre, working in association with the tuberculosis hospital at Nonburi, about 15 kilometres from Bangkok It forms part of the division of tuberculosis control headed by Dr Prakorb Visalvet, and on the medical side Dr Nadda Sriyabhaya is the physician in charge

The average number of deaths attributed to pulmonary tuberculosis in Thailand is about 10,000 a year, giving a mortality-rate of about 60 per 100,000, but the number among the 900,000 inhabitants of Bangkok is 1500 (or about 200 per 100,000), and this suggests that outside the capital many cases go unrecognised because facilities for diagnosis are lacking The percentages of positive reactions obtained (with 5 T U of purified protein derivative) in rural areas (5,166,363 persons) and Bangkok (111,727 persons) are

---

[1] Benatt, A J *Lancet*, 1956, i, 737

Age-group	*Rural*	*Bangkok*
1–6	16·6	32·9
7–14	40·4	68 1
15 and over	78·5	88·5
Total	51·9	71 9

On mass radiography of some 30,000 people in Bangkok and its neighbourhood during 1953–55 it was found that on miniature film about 5% of the population of Bangkok had an abnormality suggestive of tuberculosis About 1% were positive on bacteriological examination

Attendances at the central chest clinic increased from 1500 a month in 1952 to 8000 in 1956 The average number of new patients visiting the clinic is now 800 a month, of whom about 40% are found to have pulmonary tuberculosis In a month this laboratory handles about 700 direct smears of sputum and about 800 cultures

Since there is only one tuberculosis hospital, with a capacity of 200 beds, facilities for institutional treatment and isolation are still very limited As a routine, tuberculosis patients receive two of the three drugs (streptomycin, isoniazid, and P.A S), and cases are supervised at home by public-health nurses who give preventive instruction to patient and family In 1956 a lay visitor was also employed to do home visiting A refill clinic was also maintained as supplementary treatment, because very few patients were able to take long enough rest

A contact clinic is held daily to give B C G vaccination to the tuberculin-negative and to examine those with positive X-ray findings Of 6299 contacts X-rayed during 1953–56, 8% were found to have pulmonary tuberculosis and 1% were positive for tubercle bacilli As another preventive measure, young children and infants in contact with tuberculosis patients are referred to a central preventorium for children, where they are isolated until B C.G has given them a positive tuberculin reaction.

A social service was started last July, and cases referred by the public-health nurses are investigated by the social worker, who reports on their needs Previously the afflicted families could get some help from the public-welfare department or charitable organisations During 1956, 102 such families received economic support besides free medical service

The mass B C.G campaign was launched in March, 1953, and 6,652,964 people had been tested, and 2,330,743 negative reactors vaccinated, by the end of 1956 The mass campaign completed, vaccination is entering on a phase of consolidation as part of the permanent national health scheme that is, the use of vaccine is to be continued on (1) contacts of tuberculosis cases, (2) schoolchildren, and (3) persons at special risk

The tuberculosis hospital at Nonburi, the only one in Thailand, was incorporated in the tuberculin project in 1951 By the end of 1956 the number of beds had risen from 75 to 200 A thoracic surgical unit was set up in 1952, and major operations in 1952–56 numbered 234 Both the central chest clinic and the hospital have become training centres for student nurses, qualified nurses, medical students, and public-health personnel To relieve the shortage of nurses a school of nursing aides was started in 1956 The course lasts a year

BLOOD-TRANSFUSION

THE Ministry of Health, in association with the Department of Health for Scotland, is shortly issuing a revised edition of *Notes on Transfusion* This follows closely the lines of the previous one (1954), but certain additions give the text greater clarity There are also some minor but important alterations for example, peanut oil has now been omitted from the diet in the treatment of transfusion reaction, and sodium lactate now replaces sodium bicarbonate in the stage of oliguria. Section IX, on the rhesus factor, has been considerably expanded and much improved Consultants as well as their juniors will find this unassuming little book of 21 pages well worth reading

DIAMOND JUBILEE OF R.A.M.C

IN honour of the diamond jubilee of the Royal Army Medical Corps, a commemorative oration, by Sir Gordon Gordon-Taylor, entitled *In Arduis Fidelis*, will be delivered in the great hall of B M.A. House, Tavistock Square, London, W C 1, on Wednesday, June 25, at 5 P M The oration will be open to the public without ticket, but past and present members of the Corps, with their ladies, are especially invited

The British Medical Association played a considerable part in the events that led to the formation of the R A M C in 1898 For some years it had pressed for reform of the Army's medical organisation, and on Jan 20, 1898, a deputation from the Association waited upon the Secretary of State for War, Lord Lansdowne, and urged the desirability of forming a single Army Medical Corps It also expressed the hope "that Her Majesty might be graciously pleased to convert such a corps by Her authority into a Royal Corps, and to give it thereby a position and prestige to which it was fully entitled."[1]

University of London

The following degrees have been awarded

M.D—H B Hewitt.
M S—A J Davies

Mr A W Wilkinson, senior lecturer in surgery in the University of Aberdeen, has been appointed to the university chair of pædiatric surgery at the Institute of Child Health

Mr Wilkinson qualified M.B in the University of Edinburgh in 1937, and took the F R.C S E three years later In the 1939–45 war he served in the R.A M C in Europe and the Far East, gaining the rank of lieutenant-colonel as officer in charge of a surgical division Returning to Edinburgh, he held the Syme surgical fellowship from 1946 to 1949, when he was awarded the gold medal for his CH.M thesis He was appointed lecturer in surgery at Edinburgh in 1951 and senior lecturer at Aberdeen in 1953 He is at present an assistant surgeon to Aberdeen Royal Infirmary and to the Royal Aberdeen Hospital for Sick Children His published work includes a book, *Body Fluids in Surgery*, and articles and chapters in books on disturbances of electrolytes and of metabolism in surgical patients

Dr A G Spencer, first assistant at University College Hospital Medical School and consultant physician to University College Hospital, has been appointed to the university readership in medicine at St. Bartholomew's Hospital Medical College

University of Alberta

Dr T A S Boyd has been appointed associate professor of ophthalmology

Hunterian Society

The society's gold-medal essay competition for 1957 has been won by Dr C A H Watts (Leicester)

The subject for the 1958 essay is Impotence The competition is open to all general practitioners Details may be obtained from the hon secretary, Dr C W Kesson, 51, Harley Street, London, W 1

World Congress on Fertility and Sterility

This congress will be held in Amsterdam from June 7 to 13, 1959 Further particulars may be had from the secretary, Dr L I Swaab, Sint Agnietenstraat 4, Amsterdam-C

Mental After Care Association

The annual meeting of this association will be held on Wednesday, April 23, at 3 P M, at the Caxton Hall, London, S W 1, when General Wilfred Kitching, international leader of the Salvation Army, will give an address

Merseyside Medical Art Society

This society was inaugurated at a dinner on April 2, when Sir Philip Manson-Bahr, president of the London Medical Art Society, gave the opening address, to which Lord Cohen of Birkenhead and Prof Brian Maegraith, the president, replied. The first exhibition, held in the Bluecoat Chambers, included works by doctors in Liverpool, Manchester, Warrington, and Southport. The society's secretary is Dr D B Mossman.

Memorial to Mr H R Segar

Mr H Roland Segar became medical superintendent of Barnet General Hospital in 1929 and medical director in 1949 He relinquished this post in 1952 but continued as consulting surgeon till his death A memorial to him is planned at the hospital, and subscriptions should be sent to Mr H D Cobbe, the treasurer, at 1, Wellhouse Lane, Barnet, Herts

Mental Health Research Fund

At the annual meeting on March 25, Lord Monckton, who is chairman of the joint national appeals organisation both of this fund and of the National Association for Mental Health, spoke of the need for the public to support research on mental disorder

"It would be easy", he said, "to criticise the Government for not devoting a larger proportion of what can be spent on research to medical research, but I have been too lately released from the Government stable to be ready to prefer this sort of criticism without going on to say what research now being undertaken ought to be abandoned to make way for this Then the criticism has been levelled that, when something between two and three million pounds is being spent by the Medical Research Council, it is wholly wrong to find them spending not more than £56,000 in the field of mental-health research in the year 1957–58, but here again I feel the difficulty (which has not deterred some critics) of pointing out what medical research funds are being spent for purposes that could be abandoned to make way for this" The real answer, he believed, lies in fostering and supporting a voluntary organisation "A marked and substantial *improvement in the response of individual members of the public* would be the most effective stimulus to further Government interest" The policy of the Fund had been to encourage more research-workers to enter this field by means of grants and fellowships, and up to last September in three years it had committed itself to spend no less than £50,000 But most of this money had come from generous contributions by the Ford Foundation, and other charitable bodies "It is, I think, a profoundly disturbing fact that, apart from such contributions, the donations and subscriptions from the British public, including broadcasts and flag-days, to the N A M H and the M H R F together, never reached £20,000 in any of the three years 1954–57"

Since last September a further £23,000 has been allocated by the fund to research projects, some being given for expenses and some *for fellowships The recipients are*

Dr Mildred Creak (psychosis in early childhood), Dr Ian Cameron (intellectual disintegration in senile dementia), Dr George Jacobides (puerperal psychoses), Dr G Ettlinger (establishment of a Primate Behaviour Research Laboratory), Dr Denis Parr (alcoholism), Mr Malcolm Piercy (cerebral localisation of intellectual function), Dr B W Richards (biochemical abnormalities in mental deficiency), Dr Michael Young (families of mental-hospital patients), Dr R T C Pratt (biochemical disturbance in endogenous depression), Dr J W B Douglas and Dr J Tizard (behaviour and social ratings of national 1946 sample of children), Dr T C N Gibbens (clients of prostitutes attending V D clinics), Dr B R Gomulicki (perception and learning in blind children), Prof E Stengel (suicide), Dr H H Wolff (psychotherapy in bronchial asthma), and Dr Steven Folkard (follow-up of patients discharged through review and rehabilitation unit)

Prof Georg Maurer, chief surgeon of the Munich hospital where members of the Manchester United football team were treated after the recent air crash, has been appointed an honorary C B E

Mr Arnold Walker has been re-elected chairman and Prof A A Moncrieff deputy chairman of the Central Midwives Board

Mr Derek Walker-Smith, the Minister of Health, has appointed Mr J T Woodlock to be his principal private secretary

A south-western branch of the Dental and Medical Society for the Study of Hypnosis is to be formed and a preliminary meeting for those interested is to be held at the Gloucester Royal Infirmary on Sunday, April 27, at 3 P M

A meeting of the Manchester Royal Infirmary Old Residents' Club will be held at the Midland Hotel, Manchester, on Saturday, Oct 4 All ex-residents will be sent particulars within the next few weeks

CORRIGENDUM *Allergy to Cow's Milk*—In this annotation (Feb 8, p 304) we implied that observations reported by C Collins-Williams were made in the U S A, whereas in fact they were made in Canada

Royal Commission on Remuneration

The Royal Commission on Doctors' and Dentists' Remuneration will hold public hearings at 11 15 A M on April 24 and 25, at 10, Carlton House Terrace, London, S W 1 Representatives of the Royal College of Surgeons of England have been invited to attend on Thursday and representatives of the Royal College of Obstetricians and Gynæcologists on Friday

---

Diary of the Week

APRIL 20 TO 26

Monday, 21st

ROYAL COLLEGE OF SURGEONS OF ENGLAND, Lincoln's Inn Fields, W C 2
5 15 P M Mr C P Wilson Malignant Disease of the Superior Maxilla
6 30 P M Sir Clement Price Thomas Carcinoma of the Bronchus.
UNIVERSITY OF LONDON
5 30 P M (National Hospital for Nervous Diseases, Queen Square, W C 1) Prof B D Burns (McGill) The Problem of Memory

Tuesday, 22nd

ROYAL COLLEGE OF SURGEONS
5 P M Mr I P Todd Physiology of Rectal Sensation and its Relationship to Disease (Arris and Gale lecture)
6 15 P M Mr Rodney Maingot Postoperative Strictures of the Bile Ducts
ROYAL SOCIETY OF MEDICINE, 1, Wimpole Street, W 1
8 P M *Medicine* Dr E R Cullinan, Dr Ffrangcon Roberts, Dr R R Bomford The Physician's Obligation to Society
INSTITUTE OF DERMATOLOGY, Lisle Street, W C 2
5 30 P M Dr P J Hare Lymphomata and Reticuloses
WEST END HOSPITAL FOR NEUROLOGY AND NEUROSURGERY, 91, Dean Street, W 1
5 30 P M Mr L C Oliver Contributions of Surgery to the Treatment and Understanding of Parkinsonism

Wednesday, 23rd

ROYAL COLLEGE OF SURGEONS
5 15 P M Mr H J Seddon Surgery of Poliomyelitis
6 30 P M Mr S O Aylett Ulcerative Colitis
INSTITUTE OF DERMATOLOGY
5 30 P M Dr J O Oliver Blood Changes in Skin Diseases
INSTITUTE OF DISEASES OF THE CHEST, Brompton, S W 3
5 P M. Mr O S Tubbs Surgery of Diseases of the Pleural Cavity

Thursday, 24th

ROYAL COLLEGE OF SURGEONS
5 15 P M Mr Wylie McKissock Surgical Treatment of Intracranial Aneurysms
6.30 P M Prof C G Rob Arterial Occlusion
INSTITUTE OF DERMATOLOGY
5 30 P M Dr W N Goldsmith Metabolic Disorders
MANCHESTER MEDICAL SOCIETY
8 P M (Staff House, University of Manchester) *Anæsthetics* Dr M W Johnstone Control of Surgical Shock

Friday, 25th

ROYAL COLLEGE OF SURGEONS
5 15 P M Mr N R Barrett Tumours of the Chest Wall
6 30 P M Mr Victor Riddell Management of Thyrotoxicosis
INSTITUTE OF LARYNGOLOGY AND OTOLOGY, 330, Gray's Inn Road, W C 1
3 30 P M Dr Imrich Friedmann Advances in Chemotherapy in Ear, Nose, and Throat Diseases
ST MARY'S HOSPITAL MEDICAL SCHOOL, Paddington, W 2
5 P M Mr John Peel Modern Cæsarean Section

Appointments

BAINBRIDGE, JEAN M, M B Durh, D OBST deputy M O H and deputy principal school M O, *Gateshead*
BROOKS, D M, M B Dubl, F R C S I part-time consultant orthopædic surgeon (with special responsibility for hand surgery), Royal National Orthopædic Hospital, London

SOCIAL MEDICINE IN DEVELOPING COUNTRIES*

CICELY D WILLIAMS
B A, D M Oxon, F R C P, D T M & H
FORMERLY ADVISER IN MATERNITY AND CHILD HEALTH, SOUTH EAST ASIA REGION, WORLD HEALTH ORGANISATION

SOME of the many definitions of Social Medicine imply that it deals chiefly with social pathology, with human beings in aggregates, and with statistical results But social medicine has its clinical application as well as its pathology It deals with individuals as well as with communities (The hermit in the wilderness and Robinson Crusoe on his island have their social attributes and implications) And there is much in human needs and experiences which cannot be expressed statistically

The fact that too great a reliance on statistics may be misleading has been shown most plainly in the developing countries, where social medicine has a great deal to teach and to learn, though statistics are at present often unobtainable Another lesson which work in these countries teaches us is the necessity, for social medicine, of a good follow-up service It is the only means of ensuring that diagnosis is complete and accurate, that treatment is adequate, and that complications and sequelæ are prevented Without it, money spent on medical services and medical researches may be squandered

The Ivory Hospital

In Europe and North America hospitals are the core of the medical world They started many centuries ago with high standards of what Milroy called "philanthropic benevolence" and they have grown into sanctuaries of scientific medicine And yet there are complaints about them Some say that the patients are submitted to a large number of investigations rather than to the individual care and human kindness which they need No one person seems to be responsible for the patient as a whole Often the teaching of students is almost entirely divorced from the realities of the circumstances in which the patient became ill and to which he will return on leaving hospital[1] Medical students and nurses during their training see mainly the institutional side of medicine they are largely unaware of the public-health services and of the social sciences In some hospitals the duty of the medical team is felt to be the application of the natural sciences, and the almoner, as an exponent of the social sciences, is excluded from her place in it

In some parts of the world medical services as a whole are backward At first sight one may be struck by the good physique of the people, but it is usual to find that the expectation of life is short, and mortality among children high The sick or sorry are not the ones to be seen swinging along the roads or laughing together in the market-place In other countries the medical services are uneven Hospitals may be found with the most modern equipment, and the most expert methods of treatment and research, while in other parts of the same town people live in squalor and disease, getting no advantage whatever from scientific medicine

In most of these countries the indigenous forms of medicine are by no means scientific In some all forms of ill health are ascribed to the malevolence of witches or to the machinations of enemies Prevention of accidents and treatment of disease generally include some sort of magical ritual At the same time these systems of medicine may employ some extremely useful drugs, and some highly expert forms of massage and manipulation They nearly all include a close personal faith in the individual practitioner, and a sympathetic understanding of the troubles of the patient.

Pill and Injection

In many regions scientific, or Western, medicine was first introduced as medical care for the expatriate European population Attention was focused on the major epidemic diseases, such as plague, cholera, and smallpox, which involve risks to all, and whose control requires both treatment and preventive organisation In the emergency of an epidemic the population must be dragooned into compliance with regulations, and there is little opportunity to employ the arts of education, persuasion, and the finer points of social medicine.

As conditions improve and these major epidemics are forgotten, attention turns to endemic diseases, such as malaria, yaws, leprosy, and filariasis Of late there has been vast improvement in the techniques for dealing with these conditions and a great many mass campaigns have been launched The basis of these campaigns is usually to devise measures that demand from the population passive acceptance rather than active cooperation People have been urged

> "Let us spray your house, this will prevent malaria"
> "Let us give you an injection, this will cure your syphilis and your yaws"
> "Let us inoculate you, this will protect you from tuberculosis"

This type of campaign has had a great deal of success It is easy to get some statistical measure of the work accomplished, which pleases the administrators Not much effort is required from the recipients, which pleases them. And those who conduct the campaigns have a sense of achievement The techniques need not vary greatly from country to country, so that little local knowledge is needed The auxiliary staff are recruited locally, and when they have mastered a few simple techniques they become valuable assistants

Sometimes these campaigns stimulate not only the control of a particular disease, but also other functions of the medical service Within a short time they may show significant results by lowering mortality and morbidity and by increasing production The campaigns may then become a spearhead for further improvements But they have a negative side which should not be overlooked They may prove costly in money and in personnel, the improvement in health may be only temporary unless campaign to control the disease is followed by continued endeavour, and the lowering of mortality may lead to an embarrassing increase in population Thus health measures may be effective and yet not improve standards of living, education, or responsibility The greatest danger is that people may get the impression that good health may be achieved by a pill or an injection They do not associate improvements with their own responsibilities or with alterations in personal and community behaviour

---

* Abridged from the Milroy lectures for 1958, delivered before the Royal College of Physicians of London on Feb 4 and 6

[1] Grundy, F, Mackintosh J M *Wld Hlth Monograph* no 34, 1957

Even though malaria has been controlled and yaws eliminated, there will still be a great deal of ill health and inefficiency The population continues to demand (and the medical department attempts to supply) antimalarial drugs for every fever, and penicillin for every other disorder The community which demands pills and injections for every discomfort, but has not been led to take an interest in improving living conditions or food habits, is sometimes more difficult to reform than one which ascribes all illness to spells and incantations

One of the results of this attitude of mind may be a pressing but irrational demand for more medical services, a demand for quantity without any respect to quality The people insist on new dispensaries at C and D, while the dispensaries at A and B are allowed to fall into disrepair, before there are enough trained staff for either A new hospital is deemed to give prestige though the staff is so inadequately trained and supervised that it can scarcely be medically beneficial Men, and to a lesser extent women, attend as outpatients for trivial complaints, invariably asking for a bottle of medicine or an injection In a country that still has a great deal of ill health, a multiplicity of second-rate or third-rate medical establishments is a serious hazard to a constructive health policy

Responsible administrators are apt to develop a cynical attitude towards the medical department "The demand for hospitals is so great that I feel we are teaching the Africans to become a nation of hypochondriacs" was a comment on one area where scarcely half the children survive to maturity Can anyone really believe that it is hypochondria that kills half the children? Or has medicine failed to justify itself? Is bad medicine driving out good?

Diseases and Patients

The Western type of medicine is by no means always acceptable Many people still prefer the indigenous or non-scientific medical practices, largely because they are more sympathetic and perhaps only a little less efficient They only turn to Western doctors when they are desperate, or as a method of appeasing another powerful *mana* Their attitude towards hospitals and medical advice may remain entirely different from that of people who have grown up in contact with the resources of scientific medicine

All over the developing countries new schools and colleges of medicine are being set up which are based on scientific or Western teaching Yet one of the weaknesses of medical training in Europe is its neglect of the social sciences and of the social factors that affect the life and health of patients These overseas schools and colleges are too often dependent on the doctors trained in this European pattern If they are out of touch with social factors in their own countries, how much more is this not true in the countries of their adoption?

Some European doctors who go overseas make the most of their opportunities to learn the local patterns of living and of ideas The missions, for instance, aim at a continuity of staff which provides time and opportunity to learn the languages and get to know the people and their problems But in many of the Government and university posts this sort of continuity is not regarded as essential or even desirable

In recent years there has been a great increase in international travel Doctors from Europe and North America have visited hospitals and universities overseas They often mention with satisfaction the operating-theatres, laboratories, libraries, and pathological museums They rarely refer to the record-keeping, the patients' food, the casualty department, or follow-up service Sometimes they do not mention paediatrics It is natural, therefore, that insufficient attention may have been paid to these matters

The result is that while European medicine has been focused on institutions, medicine in developing countries has been largely focused on diseases Once a condition is recognised as being prevalent, it is labelled as "a public health problem", and approached by mass methods But mass surveys, mass treatment, mass feeding programmes, mass health education, and environmental sanitation are expensive and not always appropriate They cannot take the place of individual care, and of consistent and careful observation The old narrow view that by using specific techniques and curing specific diseases we would all achieve health has proved wrong It is a mistake to look only for mechanical answers to what are mainly human problems

Dangers of Specialisation

It is increasingly realised that the human being must be treated as a whole, and the family as a unit To disregard man in his environment or to ignore the importance of his place in the community or within the family is to invite complications Yet, with the rapid development of the biophysical sciences, medicine is more and more divided into highly specialised techniques Some of the specialisations lead to rapid advances in research, but some are shortlived and have only a limited contribution to make

The more a subject becomes specialised, the more it tends to pursue its own aggrandisement and perpetuation—sometimes irrespective of the general needs of the community, and the general resources of medical care Each procedure demands from the patient fresh personal contacts which are in themselves exhausting . Records have to be multiplied—collaboration becomes time consuming But the real danger arises when the narrow specialties try to direct policy and exclude the consideration of other important philosophies

In medicine the multiplication of workers has tended to separate the scientific from the social disciplines and preventive from curative medicine In this country we have a large, expensive, and elaborate medical organisation which has been remarkably successful in dealing with disease, disability, and incompetence, but it is based on strong historical traditions, on a highly industrialised society, established law and order, and on an acceptance of social responsibility If they go overseas, doctors and nurses who have trained in this country, may find it hard to adapt themselves to new conditions where the pattern of medical care is simpler and where they must be prepared to deal with large numbers of very common diseases The true need of the developing countries is for medical services with a broad outlook that will have curative, preventive, and social functions Too much specialisation is expensive and inappropriate Experience has shown that specialisation in certain diseases often leads to the neglect of others

At the administrative level, too, there is still an inclination to call in a new specialist for every problem If health education is needed, then a "health educator" is employed If malnutrition is recognised, then a "nutrition worker" is thought to be necessary Yet these experts may have little or no clinical training, and are often not qualified to give health education or nutritional treatment to individual patients It is said that the doctors and nurses are not trained, or not interested in, or have no time for these things If so, it is preferable to employ more doctors and nurses and to give them better training The health educator and the nutrition worker may indeed be of service at the community level, but doctors and nurses should remain responsible for clinical diagnosis and management

In some places where the medical services are accepted only reluctantly a social anthropologist is called in to investigate and analyse popular resistance Many of the observations made by the social anthropologists could well have been reported by the doctors and health nurses working in the area, if ever they had been encouraged to do so Doctors and nurses have a great advantage over the research-worker, who is often only able to define the status of a population with respect to resources and conventions A medical staff, who have gained the confidence of the people among whom they work and live, can also observe the dynamics They can observe the response to improved health, the reaction to changing opportunities, and the variations with which individuals and families adapt their behaviour to new concepts

Many social workers from overseas come to train in Europe Commonly they go home with the idea that an expensive pattern of social security is of the highest priority They may feel that institutions should be provided for delinquent, neglected, and handicapped children But in the United Kingdom over 60% of the children who have to be taken under care are derelict because of some problem in health, and in countries where disease is far more prevalent than here a very much larger proportion of so-called social problems are in fact due to ill health or neglected health In most primitive societies there is a tradition of kinship and family responsibility, and it is more important to build on this than to provide institutions

The progress of medicine in the developing countries must in fact depend largely on its social content. Too much specialisation has led to the separation of clinical and social work, but expanded medical services would lead to the prevention of social complications and disasters

Custom and Nutrition

Nutrition is closely bound up not only with economics and geography but also with social *mores* Too often nutritional diseases are attributed to an absence of food, and the fact that the nutritional state is the end-product of dietetic, infective, parasitic, psychological, and even purely social factors is overlooked

Wherever malnutrition exists, it is always the children who suffer most Because medicine in the developing countries has given so little attention to the children the existence and the gravity of malnutrition has been overlooked for too long

A number of surveys have been made, but they are of limited value They often concentrate on schoolchildren, an age-group which is relatively healthy Though they record the stigmata of chronic or past malnutrition they rarely include the acute case Few data are given about the factors that have led to the condition

In some places true food shortage exists Sometimes this shortage is permanent, but in many places it is seasonal It may be due to poor storage facilities It is sometimes due to improvidence The people know how to make biltong and pemmican, but custom demands that when game is killed in hunting, or when cattle are killed for a celebration, these should be eaten in vast quantities They know how to store their grain, and how to preserve green food for the dry season, but it is not done It is social custom which demands enormous feasting on certain occasions, but which tolerates near-starvation between whiles This is a pattern of behaviour which adults appear to enjoy but which has a serious effect on young children

Sometimes irrational religious or traditional sanctions are associated with food Eggs, for instance, which are known to be nutritious and digestible, and very useful in feeding young children, are almost universally avoided Strict vegetarians, such as Hindus, will not use them The Malays say they produce worms, in some parts of Africa they are said to induce sterility, in others they are credited with causing baldness, and in others again they are said to make the child into a thief In some places they are simply regarded as tasteless and useless except for sale to Europeans

Not only is the choice of food at fault Sometimes it is the preparation, presentation, and timing Good cereals may be used, but they are insufficiently ground, pounded, winnowed and cooked, so that they are indigestible Enormous quantities may be given at one meal, and sheer distension may impede digestion and absorption

In some parts of the world children are given food that is so highly seasoned with pepper that its effect on the mucosa must be excoriating I am often told "But he is used to it", but nobody can say how many children have died in the process of "getting used to it"

In all the countries where malnutrition is common it will be found that there is much dyspepsia and gastro-enteritis among the children The dyspepsia often passes unnoticed, because the parents regard gross abdominal distension and pain as normal in children at weaning The same may be true of attacks of diarrhœa and enteritis It is often hard to get adequate laboratory diagnosis, but some of these cases of diarrhœa are due in fact to the physical properties of the food which cause irritation This may, of course, render the intestines more liable to invasion by pathogens

There is still much uncertainty about the effect of helminths Heavy infection with the ancylostome is known to produce anæmia Some claim that Negroes have a considerable racial resistance to hookworm [2] This is difficult to believe I wonder whether it will not prove on closer observation that many people have an acquired immunity towards helminths Those who have had mild infection in their early years may therefore show greater immunity in later life

Roundworms are sometimes said to be harmful only when they are present in large numbers I have myself seen serious complications due to roundworms But I believe that when one can observe children over long periods it will be found that the presence of one or two ascaris in the intestinal tract of a young child may interfere with digestion and absorption to a degree that may seriously affect the nutritional state

Sometimes the distribution of the food within the family is at fault Sometimes the nutritional state is poor because of other disorders, among which may be conditions as diverse as tuberculosis, scabies, and maternal deprivation

A great deal of trouble and money is now being spent on increasing food-supplies The distribution of supplementary foods is being organised But the provision of supplementary foods is symptomatic, not ætiological, treatment It does not in itself teach parents how to care for their children, or how to select or prepare their food, nor yet does it treat or prevent recurrent attacks of dyspepsia, diarrhœa, or helminthiasis It is personal advice and encouragement from someone who has won the confidence of the patient that is the most potent source of education

---

[2] Keller, A E, Leathers W S, Ricks, H C *Amer J Hyg* 1934, 19, 629

The most serious aspect of malnutrition in many places is not the absence of food, but that the doctors and medical auxiliaries have not been sufficiently trained to diagnose nutritional diseases, more especially in the early stages when they are still eminently treatable

There is lack of hospital facilities for children with malnutrition Even where there are beds for children, diagnosis and treatment is sometimes inadequate and there is little attempt to educate the parents Not enough is done to discover the basic causes behind the malnutrition, and the follow-up and continued supervision is poorly organised

Protein deficiency is now looked on as a serious and widespread nutritional defect, and a great deal of international effort and money is being devoted to the supply of more proteins on a massive scale I do not agree with Waterlow [3] when he says

> " The prevention and control of protein deficiency in man is limited by the lack of scientific knowledge, not only in agriculture but also in medicine and physiology "

For years we have known how to diagnose and prevent protein malnutrition, and how to cure all but the moribund patients It is not scientific knowledge that is lacking it is the will to organise the necessary services, and give adequate training to the necessary medical personnel

Thousands of pounds are spent each year on high-level scientific conferences, on elaborate research, and on mass methods of feeding But we fail to find methods of application and we fail to give help where help is needed More attention to the social aspects of nutrition would ensure better diagnosis of the causes, better facilities for treatment, and better supervision to prevent recurrence

(To be concluded)

ON THE FAT-MOBILISING ACTIVITY OF HUMAN URINE

THE DEPARTMENT OF MEDICINE,
MIDDLESEX HOSPITAL MEDICAL SCHOOL, LONDON, W 1

With the assistance of IVOR SMITH, Ph D Lond , F R I C
Lecturer in Biochemistry, Courtauld Institute of Biochemistry, London, W 1

PREVIOUS studies on obese people (Kekwick and Pawan 1953, 1956, 1957) have shown that if the calorie content of the diet is kept constant, the rate of weight loss varies considerably with alterations in the composition of the diet (fig 1) Evidence was also put forward to suggest that the decrease in body-weight could be accounted for by loss of body fat and water It appeared that a mechanism existed for controlling the mobilisation of depot fat which must be sensitive to changes in the composition as well as the calorie content of the diet Such a mechanism should be operating at its maximum during fasting, and if any hormonal agent were involved it should be detectable in the urine Indeed Weil and Stetten (1947) had already shown the presence of a fat-mobilising substance in the urine of fasting rabbits

It was decided therefore to study the effect on fat metabolism of urine collected from healthy people during periods of fasting For comparison, urine was obtained from the same subjects when taking a normal mixed diet Batches of urine were collected and extracted in an identical manner The extracts were injected into mice, which were used as the experimental animals throughout

Method of Extraction

Subjects were fasted for 36 hours, urine being collected during the last 24 hours of this period

The urine was acidified to pH 5 3 with hydrochloric acid, 2 vols of ethanol was added, and precipitation was allowed to proceed for at least 16 hours The precipitate was filtered off, washed twice with ethanol-water mixture (2 1) at pH 5 3, dried at room temperature, and extracted with 0 5% aqueous sodium carbonate It was then centrifuged and the supernatant fluid obtained This alkaline extract was reprecipitated at pH 5 3 with ethanol and the precipitate extracted again with sodium carbonate The solution was neutralised just before injection The final volume of extract was made up to 10 ml for each 24-hour urine sample

Results

Experiment I Effect of Extracts on Liver Fat Content

Three separate groups of mice were used with each extract tested The first group received 0 5 ml of normal saline, the second 0 5 ml of urine extract from people taking a normal diet, and the third 0 5 ml of urine extract from the same people when they had been fasting All injections were given subcutaneously and the animals were killed after a 6-hour fast The liver fat was then estimated by the method of van de Kamer et al (1949)

It is clear from table I that, in every experiment, the urine extracts obtained during fasting produced a significant increase in liver fat Animals receiving the urine extracts from the same people when on a normal diet had liver fat values very similar to those found in the control animals The increase in liver fat was linearly related to the dose of urine extract over the range 0 025–2 5 ml per 100 g (table II, col 2, and fig 2)

Since many substances can produce fatty livers in animals through a toxic effect on the liver itself, further evidence was needed to support the view that the effect of the fasting urine extracts was due to increased mobilisation of fat from the fat depots Table II (cols 3, 4, 5) shows the effect of fasting extract on blood-lipids It can be seen that phospholipids, cholesterol, and " total lipids " all increased more or less progressively with increasing doses of extract Further confirmation of the presence of fat mobilising activity in the extracts was obtained from studies in which radioactive fat was used

Experiment II Fat Turnover Studies

Mice were given a diet containing glyceryl tripalmitate-1-^{14}C (2 μC daily) for 3 days On the 4th day the animals received injections of saline or urine extracts After a 6-hour period, during which food was removed, the animals were killed and the fat separately extracted from the liver, subcutaneous tissue, intestine with mesentery, and the rest of the body (residual carcass) The concentration of ^{14}C (specific activity) in the fat from each source was measured in a windowless gas-flow counter

It was found that the activity of the liver fat was always much higher than that of the subcutaneous and residual, carcass fat in control animals injected with saline (table III) There was a large variation, owing presumably to differences in the amount of labelled fat ingested and absorbed by each animal The effect of the urine extracts was nevertheless remarkably well defined (fig 3) In the case of the subcutaneous and liver fat the values obtained with the non-fasting extract did not differ significantly from the controls The fasting extract, on the other hand,

---

3 Waterlow J W *Ind med J* September, 1956, p 167

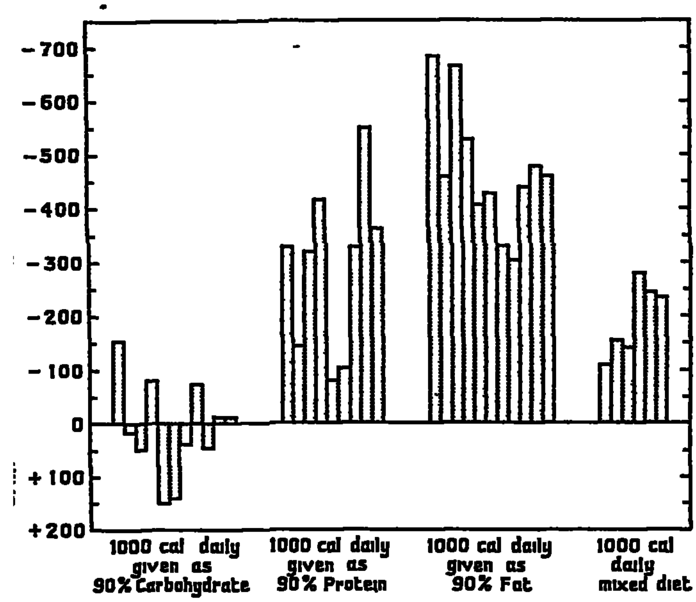

Fig 1—Effect of alteration in the composition of 1000-calorie diets on body-weight of obese people. Daily weight changes are the mean figures of 5-9 day periods on each diet.

produced a fall in the specific activity of the fat from both sources This extract also produced a fall in the activity of residual carcass fat as compared with saline The effect of non-fasting extract on residual carcass fat could not be determined clearly owing to the wide scatter in the results obtained

The total weight of subcutaneous and residual-carcass fat did not change appreciably Therefore the decrease in specific activity after the fasting urine extract seems to be due to an increased turnover of fat that is to say, both mobilisation and deposition of fat have been speeded up, the newly deposited fat being derived from unlabelled precursors An alternative interpretation must be mentioned that the recently administered fat, containing the radioactive label, had been more readily mobilised than the remainder of the depot fat This view could account for the fall in specific activity of the depot fat, and would be consistent with the failure to detect a fall in the total amount only if the actual quantity mobilised was too small to be measured

TABLE I—EFFECT OF INJECTIONS OF SALINE SOLUTION AND HUMAN URINE EXTRACTS ON MOUSE LIVER FAT

Source of urine	No of mice used	Liver fat %			% increase $\left(\frac{F-C}{C}\times 100\right)$
		Saline solution (C)	Non-fasting urine	Fasting urine (F)

In the case of the liver, the increase in the total amount of fat after fasting extract must be taken into account. The fall in specific activity here must indicate dilution of the relatively strongly labelled liver fat by transfer of low-activity fat from the depots or increased hepatic synthesis of fat from unlabelled sources

Taken together, therefore, measurements of the concentration of ^{14}C in fat from different regions provide further evidence that the fasting extracts contain a fat-mobilising substance

Evidence was also obtained from this experiment that the effect of this material is not merely to transfer fat from the depots to the blood-stream and the liver but also to increase the rate of fat catabolism (Table II [col 6] shows that the blood ketones were increased following injections of the extract) When mice were fed radioactive fat for 3 days and on the 4th day killed 6 hours after an injection of saline, about 60% of the administered activity could be recovered in the body fat (table IV) After injection with urine extracts from people eating a normal diet, the percentage recovered was similar After injection with urine from the same subjects fasting, however, no more than 25–35% of the administered activity could be recovered as fat. Since the total amount of fat in these animals was not significantly less than in the controls, it appeared that the "fasting" urine extracts were capable of increasing the total metabolic turnover of fat in the animal as a whole

TABLE II—EFFECT OF GRADED DOSES OF "FASTING" URINE EXTRACT ON LIVER FAT, BLOOD LIPIDS, AND BLOOD KETONES 4 MICE WERE USED AT EACH DOSE LEVEL MEAN VALUES AND PERCENTAGE CHANGES COMPARED WITH THE SALINE CONTROLS

Dose of extract (ml.)	Liver fat g per 100 g	Blood lipids			Blood ketones (mg per 100 ml)
		Lipid phosphorus (mg per 100 ml.)	Total cholesterol (mg per 100 ml.)	"Total lipids" (mg per 100 ml.)	
Saline solution	3·9 (0)	5·4 (0)	57 (0)	430 (0)	0·9 (0)
0·01	4·1 (+5)	5·9 (+9)	53 (−7)	458 (+7)	1·5 (+66)
0·1	5·6 (+44)	6·1 (+13)	60 (+5)	500 (+16)	2·2 (+144)
1·0	7·1 (+82)	6·7 (+24)	63 (+10)	495 (+15)	2·6 (+189)
10·0	7·5 (+92)	7·1 (+31)	79 (+38)	580 (+35)	3·9 (+255)

Experiment III Effects of Repeated Injection on Body-weight and Carcass Composition

Three groups of mice were injected subcutaneously on alternate days for 17 days—the first group with saline solution,

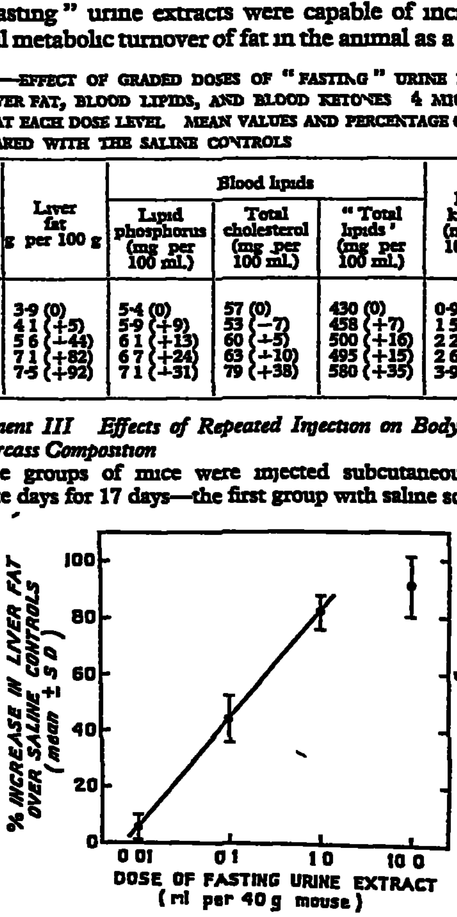

Fig 2—Dose-response curve (semi-logarithmic) showing effect of fasting urine extract on liver fat content (4 mice at each dose level)

TABLE III—SPECIFIC ACTIVITY OF FAT EXTRACTED FROM VARIOUS TISSUES AFTER FEEDING GLYCERYL-TRIPALMITATE-1-^{14}C 2 MICROCURIES GIVEN DAILY FOR 3 DAYS TO 20 MICE ANIMALS KILLED ON THE 4TH DAY 6 HR AFTER AN INJECTION OF SALINE SOLUTION

—	Counts per min per mg fat (mean ± 2 S E M)
Liver	997 ± 92
Intestine and mesentery	702 ± 164
Subcutaneous tissue	183 ± 16
Residual carcass	252 ± 28

the second with urine extract from people on normal food intake, and the third with extract from the same subjects when they had been fasting

Table v (col 4) shows that the group injected with saline solution lost a little weight, possibly because of the handling of the animals The group receiving the non-fasting urine extract also lost a little weight With the fasting urine extract there was a significantly greater mean loss of weight, amounting to over 6 g per mouse at the end of 17 days This finding again might signify no more than that the fasting urine extract contained a substance toxic to mice The animals, however, remained ostensibly in good condition, in particular, their appetite was unimpaired (Medical Research Council diet no 41 was fed ad libitum the difference between the weight of food offered and the weight remaining gave the amount consumed) This seems to be strong evidence against the presence of a toxic substance in the fasting urine extract Such a substance would be expected to impair appetite to a measurable degree

TABLE IV—EFFECT OF SINGLE INJECTIONS OF "FASTING" URINE EXTRACTS IN INCREASING TURNOVER OF WHOLE BODY FAT SERIES A (60 MICE) RECEIVED EXTRACTS 2B (TABLE I), SERIES B (49 MICE) POOLED EXTRACTS 9–20

Material injected 6 hr previously	Fat extracted from whole carcass, including liver			
	Total amount of fat as % of saline control (mean and S E D)		% of injected ^{14}C recovered (mean and S E M)	
	Series A	Series B	Series A	Series B
Saline solution	100	100	60 0 (±7 1)	52 6 (±8 9)
Non-fasting urine extract	98	94 (±11)	50 8 (±9·4)	59 5 (±14 8)
Fasting urine extract	111 (±11)	105 (±6)	37 2 (±4 1)	25 3 (±4 0)

The animals were killed at the end of the period and the carcasses analysed Table v, col 5, and fig 4 show that the weight-loss was entirely accounted for by loss of fat and water

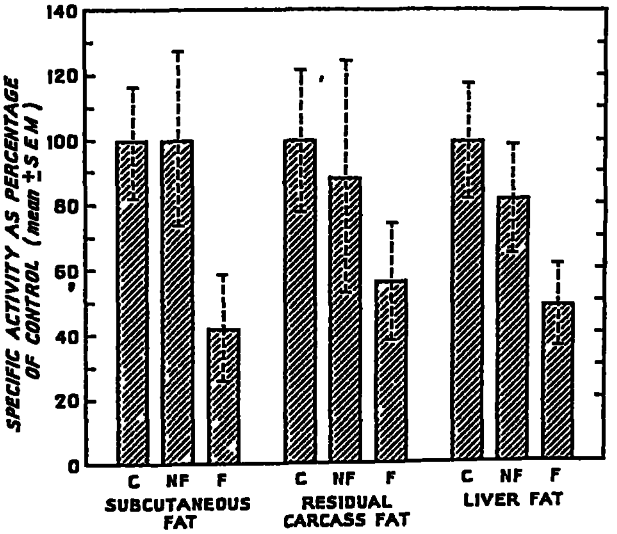

Fig 3—Effect of urine extracts on specific activity of subcutaneous, residual-carcass, and liver fat C, saline control, NF, urine extract (non-fasting) F, urine extract (fasting)

It is, we contend, reasonable to assume from this experiment that extracts from urine of people who have been fasting contain a substance capable of accelerating fat catabolism in mice, producing loss of weight without any significant reduction in the calorie intake of the animals and without any apparent impairment of their health or appetite

TABLE V—EFFECT OF REPEATED INJECTIONS OF SALINE OR URINE EXTRACT ON BODY WEIGHT AND CARCASS COMPOSITION EACH ANIMAL RECEIVED 0 5 ML ON ALTERNATE DAYS OVER A 17-DAY PERIOD

(1)	(2)	(3)	(4)	(5)		
Material injected (volume (0 5 ml)	No of animals	Mean food intake (% of control)	Body-weight change (g per mouse per day) (mean ± S E M)	Carcass analysis (% body weight)		
				Fat	Water	Protein
Saline solution	30	100	−0 109 (±0 055)	13 5	64 3	11·9
Non-fasting urine extract	10	101	−0 118 (±0 042)	13 4	63 7	11 8
Fasting urine extract	20	98	−0 360 (±0 049)	11 8	66 1	13 6

Experiment IV Examination of Urine Extracts by Paper Chromatography

Attempts were then made to identify the active substance The two extracts, one from people taking a normal diet and the other from the same people after fasting, were examined by paper chromatography When acetic-acid/water mixtures were used as the solvent, a substance was found in the fasting urine extract which was absent from the non-fasting extract This could be located with ninhydrin

Larger amounts of material were separated by chromatography and then eluted from the paper The eluate was dried and made up to the original volume as applied to the paper This material was injected into mice and again found to increase the liver fat (table VI) The remainder of the paper and, in particular, adjacent areas were separately eluted and these eluates injected into mice Table VI also shows that the active substance was absent from other parts of the paper

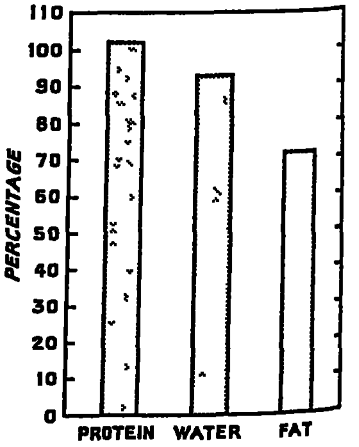

Fig 4—Total body protein, water, and fat of mice who had received fasting urine extract over a 17-day period, expressed as % of initial values (Initial composition of experimental group assumed to be the same as final composition of control groups)

It appeared possible, therefore, by means of paper chromatography to separate material from the urine extracts of healthy people who had been fasting which was absent from the urine of the same subjects taking food This partially purified material had the property of increasing the fat content of the livers of mice, under the same conditions as in experiment I

TABLE VI—EFFECT ON LIVER FAT OF ELUATES FROM VARIOUS PORTIONS OF THE FASTING URINE CHROMATOGRAM

—	Mean liver fat (g per 100 g liver)	% increase
Saline control	5 1	—
Urine extract F	8 7	71
After chromatography		
Saline control	5 1	—
Active ' spot	7 7	51
' Tail " of spot	5 5	8
" Inactive ' paper	5 3	4

Other Investigations

Preliminary investigations were also undertaken to determine whether this substance was present in human urine in other conditions associated with weight-loss, besides complete fasting

In three obese patients, who were kept throughout periods of 2 or 3 weeks on diets of equal calorie value (1000 calories), weight-loss was greatest when the calories were given mainly in the form of fat, losses were smaller with high-protein diets (table VII) When carbohydrate made up the major part of the calorie intake, little or no weight was lost (cf fig 1) When urine extracts were tested in mice, it was found that activity in the liver-fat test was again greatest during the high-fat periods and least during high-carbohydrate periods Moreover, material resembling that found in fasting urine could be demonstrated in the urine by paper chromatography during high-fat and high protein periods, but could not be detected when calories were supplied in the form of carbohydrate

Data on two patients with widespread malignant disease, one of whom was taking a fairly normal diet, are also included in table VII In both patients the urine was active in increasing mouse liver fat and the chromatogram was positive

Conclusions

It is conceded that any one of these experiments viewed in isolation is open to a different interpretation from that offered and indeed to possible objections Nonetheless, when the evidence is examined as a whole, it is difficult or impossible to escape the conclusion that a substance or substances exist in the urine of healthy people who have been fasting, and probably in other conditions, which has the properties of mobilising depot fat in mice, increasing the amount of fat in the liver, and increasing the rate of fat metabolism This substance, when given over a period of time, produces loss of body-weight in the animals without impairing their appetite

TABLE VII—EFFECT OF URINE EXTRACTS ON MOUSE LIVER FAT AND RESULTS OF CHROMATOGRAPHY IN 3 OBESE PEOPLE ON 1000-CALORIE DIETS AND IN 2 PATIENTS WITH MALIGNANT DISEASE

(1) Patients (all female)	(2) Diets	(3) Body-weight change (kg per week)	(4) % increase in mouse liver fat	(5) Chromato-graphic evidence
1 Obese	90% carbohydrate 90% fat	−0 8 −2 8	7 47	0 +
2. Obese	90% carbohydrate 90% fat 90% protein	−0 4 −2 5 −0 5	2 73 39	0 + +
3 Obese	90% fat 90% protein 90% carbohydrate	−2 3 −0 8 +0 1	65 50 13	+ + 0
4 Terminal malignant disease	Appetite very poor	−1·9	69	+
5 Carcinomatosis (breast)	Eating fairly normal diet	−0 4	43	+

Summary

A substance or complex is present in the urine of healthy people who have been fasting, which on injection into mice

1 Increases the total amount of fat in the liver

2 Mobilises fat from the fat depots

3 Appears to increase the total metabolic turnover of fat in the animals

4 Causes weight-loss without depressing appetite when given over a period of time, the loss being in the form of body-fat and water

The active material has been partially purified by paper chromatography

This substance or complex cannot be detected in identical extracts made from the urine of the same people when they are taking a normal diet

The substance, called here fat-mobilising substance, seems to be present in the urine in certain conditions, besides fasting, associated with weight-loss

We should like to acknowledge our indebtedness to the clinical research committee of the Middlesex Hospital for so generously placing facilities for keeping animals at our disposal, and to Mr A C Catchpole for his assistance in looking after them, to Sir Charles Dodds for his advice and criticism, and to Dr J F Tait for his advice on radioactive technique

STAPHYLOCOCCAL PERITONITIS IN THE NEWBORN

D W BEAVEN
M B N Z , M R C P , M R A C P , M R C P E
SENIOR MEDICAL REGISTRAR, CHRISTCHURCH HOSPITAL, NEW ZEALAND

MINOR staphylococcal infections in the neonatal period have been increasingly reported in recent years Forfar et al (1953), commenting on this increase, drew attention to the potential dangers of such infections Reports by Sullivan (1956), Disney et al (1956), Beaven and Burry (1956), and Forbes and Emerson (1957) suggest an increasing incidence of staphylococcal pneumonia in young infants in Australia, Britain, New Zealand, and the United States respectively

Although in this age-group there is an increased incidence of all staphylococcal lesions, no report on staphylococcal peritonitis can be found in the English literature over the past ten years Nana and Mircioiu (1948) reported two cases of primary enterococcal peritonitis, and Ryan (1953) cited one case of primary staphylococcal peritonitis at the Edinburgh Royal Infirmary in 1929–53

Five cases of staphylococcal peritonitis in the neonatal period are now reported because the clinical picture was constant enough to make diagnosis possible in the three later cases These babies were all admitted to the Christchurch Hospital in the two years before July, 1957

Case-reports

Case 1—A boy, aged 14 days, born at full term, was admitted on April 29, 1956, with twenty-four hours' history of refusal to feed, pallor, and abdominal distension

On examination he was pale, listless, and acutely ill, with grunting respirations, peripheral cyanosis, and a uniformly distended tender abdomen. Bowel sounds were absent Scattered papules and two pustules on the legs suggested staphylococcal septicæmia The chest was clear on auscultation

Treatment was started with oxygen, penicillin, and intramuscular chloramphenicol, but the baby died in three hours

Necropsy revealed well-marked generalised peritonitis due to *Staphylococcus aureus* resistant to penicillin and the tetracyclines, but sensitive to other antibiotics

Case 2—A girl, aged 20 days and weighing 5¹/₂ lb, who was born three weeks prematurely, was admitted on Aug 20, 1956, with thirty-six hours' history of listlessness and twelve hours' history of vomiting Severe abdominal distension had been noticed during the twelve hours before admission, but only one offensive motion had been passed Greatly reduced bowel sounds were heard over this distended tympanitic abdomen

Treatment—A provisional diagnosis of meconium ileus led to treatment with subcutaneous fluids and laparotomy Operation by Mr J Ardagh revealed purulent peritonitis Despite a diligent search no local cause for this was found Peritoneal swabs grew *Staph aureus* resistant to penicillin and the tetracyclines but sensitive to chloramphenicol and erythromycin Treatment with intramuscular erythromycin 100 mg six-hourly was started After a stormy postoperative course, with an infected wound and severe anæmia requiring infusion with packed red cells, the baby was discharged on Oct 9, 1956 There was no history or evidence of antecedent skin infection

Case 3—A girl, aged 13 days, was admitted on Dec 6, 1956, with twenty-four hours' history of refusal to feed and vomiting For two days she had had no bowel motion, and increasing abdominal distension had been noticed

On examination her abdomen was tender and distended, and bowel sounds were absent No skin lesions were detected after careful search

Treatment—Primary staphylococcal peritonitis was diagnosed, and laparotomy and drainage of the abdomen were done Peritoneal swabs grew *Staph aureus* resistant to penicillin and streptomycin but sensitive to all other antibiotics tested Intravenous aureomycin 250 mg b i d was first used, and then erythromycin 100 mg six-hourly, both orally and by intramuscular injection

Progress—Recovery was slow and complicated by staphylococcal subcutaneous abscesses, hence the baby was not discharged from hospital until Jan 23, 1957

Case 4—A girl, aged 21 days, had developed in the first week of life a small pustular lesion on her left hand This lesion had been incised and painted with 1% gentian-violet solution She was admitted to hospital on Jan 26, 1957, with a week's history of apathy and forty-eight hours' history of increasing abdominal distension and vomiting

On examination she was pale and breathless, with distended tympanitic abdomen in which no bowel sounds were heard

Treatment—Staphylococcal peritonitis was provisionally diagnosed and treatment with intravenous erythromycin and fluids started, but the baby died within three hours of admission

Necropsy confirmed the staphylococcal peritonitis and revealed also a liver abscess The *Staph aureus* was resistant to penicillin, streptomycin, and the tetracyclines but insensitive to chloramphenicol and erythromycin The necropsy findings showed that umbilical infection had spread to the liver and peritoneum, despite the absence of any clinical evidence or history of umbilical sepsis

Case 5—A boy, aged 7 weeks, was admitted on Nov 14, 1957, with three days' history of abdominal pain He had not had any skin lesions, but his mother had had mastitis severe enough to necessitate weaning a few days before the onset of the baby's illness

On examination the baby had a high swinging temperature, and distended abdomen, with reduced bowel sounds

Treatment—Laparotomy five days after admission revealed generalised peritonitis, which gave a heavy growth *Staph aureus* only partially sensitive to penicillin but sensitive to all other antibiotics tested Considerable improvement followed six days' treatment with chloramphenicol Convalescence was complicated by subcutaneous abscesses, suggesting spread of the infection via the blood-stream

Discussion

In the five years before 1955 there were few recorded deaths from staphylococcal pneumonia or septicæmia in infants admitted to the Christchurch Hospital Since Beaven and Burry (1956) reported an explosive outbreak of staphylococcal pneumonia in newborn babies in a Christchurch maternity hospital there has been an increased number of all staphylococcal infections in this age-group From that date (December, 1955) to July, 1957, thirty-five newborn babies were admitted to the Christchurch Hospital with staphylococcal infections Five of these had staphylococcal peritonitis and showed a remarkably constant clinical picture The following features enabled a strong provisional diagnosis of staphylococcal peritonitis to be made in the last three cases (1) a history of vomiting unassociated with diarrhœa, (2) a tender distended tympanitic abdomen with reduced or absent bowel sounds, (3) pre-existing staphylococcal skin lesions (present in case 4 and in case 5's mother)

In case 4 the infection was probably via the umbilical cord, because histological sections of the cord showed bacteria and a liver abscess was present, but there was no superficial evidence of umbilical sepsis on clinical examination

In the other cases it is reasonable to assume that the bacteria were blood-borne (no blood was cultured) A previous history of staphylococcal infection would suggest septicæmia

These cases of peritonitis did not develop before the 14th day of life Murray et al (1953) have shown that transmitted maternal antibodies appear to protect the baby in the first 2 weeks of life

Differential diagnosis—Rickham (1955) reported 17 cases of peritonitis in newborn babies in three and a half years and suggests that peritonitis is not rare in this age group The more common causes are perforated or gangrenous bowel and meconium ileus, but staphylococcal peritonitis is one cause of acute bacterial peritonitis and should be considered when there is a history of other staphylococcal lesions The tympanitic silent abdomen should prevent confusion with respiratory infections in these cyanosed and distressed babies, who often had rapid grunting respirations

Treatment—Adequate treatment with the correct antibiotic seems to influence the prognosis, and on present knowledge erythromycin 150–200 mg per kg of body weight daily, alone or in combination with novobiocin 100 mg per kg of body-weight daily, is preferred Laparotomy in cases 2, 3, and 5 allowed drainage of the pelvis and is necessary to exclude the commoner causes of peritonitis Dehydration and electrolyte imbalance from vomiting may need to be corrected before operation In severely shocked and collapsed babies there is a place for the use of intravenous hydrocortisone

Summary

Five cases of "primary" staphylococcal peritonitis in newborn babies are described

A silent or near silent abdomen which was tender, tympanitic, and distended was uniformly present

This uniform picture and the preceding history were helpful in diagnosis

I wish to thank Dr J F Landreth, senior pediatrician, Christchurch Hospital, under whose care these cases were admitted, for his interest and helpful criticism and for permission to publish, Mr J Ardagh, who operated on cases 2 and 3 and has also offered

helpful criticism, and Dr D T Stewart, director of the department of pathology, for the necropsy reports

"ENCEPHALITIS TREMENS"

JOHN WRIGHT
M.B Leeds, F.R C S
GENERAL PRACTITIONER, SOMERSET

DAVID C MORLEY
M D Cantab, D C H
PÆDIATRICIAN, METHODIST MISSION HOSPITAL, ILESHA, WESTERN NIGERIA

Two outbreaks of encephalitis with widely differing features and natural history have lately been described, one from Sierra Leone (Rose 1957) and the other from a London hospital (Medical Staff of the Royal Free Hospital 1957) We here record 25 cases of encephalitis seen at the Methodist Mission Hospital, Ilesha, Western Nigeria, which presented with characteristics different again, but in which the clinical picture was so distinct as to suggest a pathological unity Neither of us had seen such a condition before and in spite of the interest, advice, and generous help of many colleagues we have been unable to come to any proven conclusions about its ætiology

Incidence

The hospital serves a rural town of about 75,000 population, and a district of about the same population again During the last two weeks of September, 1956, 14 patients were admitted with a syndrome whose chief feature was tremor, and during the latter half of October, a further 11 patients were admitted with the same condition That all 25 cases formed a clinical unity, one could not doubt, for they were strikingly similar in many respects Since we became aware of the condition, we have been able to trace the records of sporadic cases in the same months of previous years, and last year (1957) more cases were seen

All the patients recovered, and we have therefore no necropsy findings, and though the epidemiology of the condition has been studied in some detail we have not been able to form any definite opinions about it

Clinical Features

These are best illustrated by the history of one of the earlier patients

A Yoruba woman (case 3), aged 24, was admitted to the hospital at 9 A M, Sept 17, 1956 She had, it seemed, been perfectly well until 8 A M the previous day, when she suddenly complained of headache and dizziness A little later she vomited, and there was also some colicky abdominal pain, but no diarrhœa After this she could not remember what happened, but relatives said that she started to " shake all over ", and that though she appeared able to hear questions and commands, she was unable to reply to them

She had a gross, coarse, rhythmical tremor of the entire body, exaggerated by sitting up and especially by standing She was conscious but unable to speak Her temperature was 99·2°F She was treated with mephenesin and magnesium sulphate by mouth, and bed rest Lumbar puncture yielded an entirely normal fluid

Next day she recovered her speech, and on the fourth day the tremors finally disappeared

The detailed histories in the other cases are given in the table, in sum, they were all characterised by

(1) Sudden onset of giddiness, followed by
(2) Vomiting, with or without abdominal pain, followed by
(3) Generalised tremors, which might or might not be followed by
(4) Aphasia, or unconsciousness (semicoma), or both

Onset of giddiness—The onset was always sudden, and no patient complained of antecedent illness Usually within an hour of the giddiness came vomiting, though in no case was this protracted and, in practically all, it had ceased on arrival at hospital Soon after the vomiting, tremor began

Tremor was the most dramatic feature of the syndrome It varied widely in severity, but had common features in all the patients Thus, it was generalised (affecting the head as well as the limbs and the trunk), rhythmical, and coarse It was exaggerated by sitting up, or by any attempt at movement and might become violent if the patient attempted to stand up The tongue often showed a similar tremor and in several cases the eyes showed conjugate and horizontal spontaneous

CLINICAL SUMMARY OF 25 PATIENTS

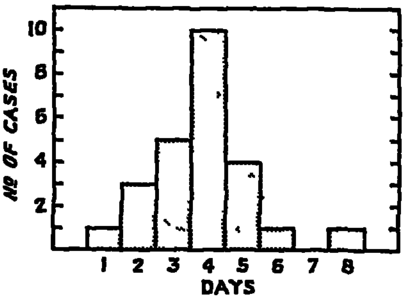
N.R =not recorded. N A =results not available oscillations All the movements abated on lying down, and disappeared during sleep Left to pursue their own course (as in many of the later cases) the tremors abated in four or five days (see figure), their duration had no relation to their initial severity Though often complaining of some residual headache, the patients thereafter appeared perfectly well, and in no case was any personality change noticed by the relatives

Consciousness —Throughout the period of tremor, many patients were mentally alert and able to speak normally, though the tremor rendered them extremely ataxic and unable to walk without support *In 8 cases, however, there was an aphasia of motor type, the patients apparently being able to hear and* understand questions and commands but unable to reply In 5 cases there was unconsciousness (semicoma), only painful stimuli drew a response, with an exaggeration of the tremor Although this semicoma lasted alarmingly in one child for eight days, its duration was usually short, and the patients returned rapidly to normal consciousness once recovery started, with no intervening period of confusion and no retrograde amnesia



Duration of tremor from onset

Speech defect —When it occurred, the defect appeared to be a true aphasia of motor type for these patients could plainly *understand commands, and their sensory perception appeared* to be normal Furthermore, physical examination showed no other abnormality of motor power in the distribution of the cranial nerves, and lip movements were normal

Fever —Many patients had a low fever in only 5 did this exceed 100°F (and then transiently), and in the majority, the temperature did not exceed 99 4°F (axillary)

Muscle tone was usually normal, or somewhat reduced, though a mild neck rigidity was noted in some at the onset

Of the *reflexes*, the abdominals could not be elicited in many patients, nor in some the knee and ankle jerks, but, in general, tendon reflexes were present and symmetrical 3 patients had transient *incontinence of urine*, and 1 needed catheterisation for two days No true nystagmus was seen in any, but conjugate oscillatory movements of the eye (of the type described above) were seen in several patients

Loss of consciousness necessitated, of course, careful adjustment of water and salt balance, but otherwise did not appear to affect the prognosis

Investigations

Lumbar puncture was performed in 12 cases, but in all a clear fluid of normal cell count and pressure was withdrawn and we gradually came to feel that it taught us little about the patients and was therefore better avoided

In 2 cases the *urine* was searched for alkaloid constituents which might point to a toxic origin, but in no case was any abnormality found

Serological examinations in 7 of the patients, by Dr James Portafield, of the virus research unit of the West African Medical Research Council, disclosed no abnormality to suggest that a virus was responsible

In fact, the condition has so far yielded little to clinical and pathological examination

Natural History

The syndrome, though *alarming*, was never fatal Both dizziness and vomiting were transient prodromal symptoms, and the vomiting was never sufficiently severe to lead to difficulties with water and salt balance The tremors were the most persistent as well as the most dramatic symptom, but they too, after a maximal onset, gradually abated and disappeared in the periods shown above Both the aphasia and the unconsciousness, where present, usually abated within three days, though in one child semicoma alarmingly persisted for eight days

Ætiology

Age and sex —All ages from childhood to adult life were represented (see table) (In this setting, any age over 20 tends to be inaccurately reported) The first part of the outbreak (14 cases, September, 1956) affected only children and women and we spent some time considering the possible significance of this The second group, however (11 cases, October, 1956) included 7 men

Timing and incidence —The outbreak was spread over a period of six weeks, and then abated, arising in two distinct "waves", which suggested an infection Conversely, however, when the times of onset were plotted (and the onset was always so sudden that this could be done), the vast *majority* were seen to lie between 7 P M and 5 A M Considering the fact that in this rural society the main meal of the day is from 5 P M onwards, these figures might suggest (if they have any significance at all) that the condition was of toxic origin An extraordinary coincidence of onset within half an hour of each other in cases 10 and 11 (who were cousins living in the same household and sharing the same food) may also suggest the same conclusion

Geographical distribution —It is of interest that all 25 patients came from Ilesha, and none from the surrounding district Ilesha is a typical densely populated Yoruba town The average number of occupants per house is of the order of 20, and in some houses *many* more Yet apart from cases 10 and *11 already mentioned, and cases 1 and 2 (mother and child)*, no 2 patients came from the same household, and the geographical distribution of patients did not point to an infection

Diet —No common factor in the patients' diets was discovered which might account for the condition There was some difficulty in recovering relevant specimens owing to the prevalent habit of finishing the food at any one mealtime But several specimens were nevertheless obtained, and analysis was kindly undertaken by Dr John Broadbent In no case was any abnormal alkaloid discovered and similar analysis of the urine of 2 of the patients failed to show any such substances being excreted

Serology —The investigations proved completely negative

The two obvious possibilities were an intoxication due to foodstuffs or other sources, and a virus encephalitis The scales seemed weighted in favour of encephalitis, but we cannot prove it The similar cases in the same months of other years—at a season when food habits are not subject to change—is another argument for the "infective" view

Discussion

Tremor was the most dramatic and characteristic feature The associated loss of consciousness and the aphasia, indicate that the lesion affects the cerebrum but the *rhythmical coarse tremors of the limbs*, and the oscillatory movements of the eyes suggest also an affection of the basal ganglia and the mid-brain This in turn suggests that, whatever the lesions may be, it is widespread and yet it is so constant on distribution that the clinical picture is remarkably uniform—a picture, moreover, which is associated with little or no change in the cerebrospinal fluid

The Lancet (1956) discussed a series of outbreaks of encephalitis, and suggested that several of these outbreaks might be grouped under the provisional title "benign myalgic encephalomyelitis" Although the term has been disputed, the classification seems at least to be temporarily valuable, in that it does cover a group of outbreaks with many common features

The Ilesha patients share three important features with that group

(1) In spite of a profound neurological disturbance, the cerebrospinal fluid remained normal in all

(2) No evidence of the causative virus (if such there be) could be found

(3) The outcome was uniformly benign

In clinical features and natural history, however, these patients present a completely different picture to that of "benign myalgic encephalomyelitis" About the only point of resemblance is "the curious jerky response of the affected muscles to volition" which, Acheson (1957) remarks, "may yet prove to be a further clinical manifestation of benign myalgic encephalomyelitis"

Summary

An outbreak of encephalitis in the Western Region of Nigeria in 1956 involved 25 patients over a period of six weeks The onset was abrupt, giddiness, followed rapidly by vomiting and characteristic tremors, were the main features of a remarkably constant clinical picture. Semicoma, aphasia, or both supervened in some patients Abnormal physical signs were few, and lumbar puncture was always negative, as were also the results of serological investigation The condition proved benign, with no permanent sequelæ Similar cases were found in the hospital records for the same season of previous years, and again in 1957

No definite conclusions could be drawn about the cause of the epidemic This syndrome was unlike anything that we—or the many colleagues we discussed it with—had seen before

Our thanks are due to our colleagues, Dr C A. Pearson and Dr David Cannon, of the Methodist Mission Hospital, Ilesha, who also saw these patients to Prof Alexander Brown, Dr M MacGregor, and Dr R Hendrickse of the department of medicine, University College, Ibadan, and to Colonel John Walters of the West African Medical Research Council, with whom the cases were discussed, to Dr John Broadbent, department of pharmacology, University College, Ibadan, who undertook the analysis of various foodstuffs, and to Dr James Portafield, virus research department, West African Medical Research Council, who undertook the serological investigations

HEPATOJUGULAR REFLUX

M B MATTHEWS
M.A, M D Cantab, M R.C.P
PHYSICIAN TO THE WESTERN GENERAL HOSPITAL, EDINBURGH,
LECTURER, DEPARTMENT OF MEDICINE, UNIVERSITY OF EDINBURGH

J HAMPSON
M.B Edin, M R C.P, M R.C.P.E
SENIOR MEDICAL REGISTRAR, WESTERN GENERAL HOSPITAL, EDINBURGH

FILLING of the external jugular veins when pressure is applied to the abdomen of patients with heart-failure was first described by a medical registrar at the Middlesex Hospital (Pasteur 1885) Rondot (1898), who used bimanual compression of the liver, realised that Pasteur was wrong in believing the test to be pathognomonic of tricuspid disease, because he observed the reflux in patients who later were found at necropsy to have healthy tricuspid valves The test became known as the Pasteur-Rondot test or, more generally, hepatojugular reflux However, pressure anywhere on the abdomen, not only over the liver, will fill the jugular veins (Lian and Blondel 1925)

In estimating venous pressure by the clinical method (Lewis 1930) pressure on the abdomen is often used to determine whether a pulsation in the neck is venous or arterial in origin A venous pulsation is almost invariably altered by this manœuvre, an arterial pulsation is unchanged

For a long time hepatojugular reflux has been regarded as a sign of cardiac failure, it has been described as probably the earliest sign in chronic cor pulmonale (Gillanders 1949, Oram 1956) If a positive hepatojugular reflux can be taken to show cardiac failure when there is no other evidence, it is important to understand the mechanisms involved and the possible sources of error For this reason we investigated the hepatojugular reflux, measuring changes in the central venous pressure in the superior vena cava with an electromanometer

In routine practice the internal jugular vein serves as a reliable manometer (Lewis 1930), and is more reliable than the external jugular vein, which may give false readings (J McMichael, personal communication) Wiggers (1914), however, emphasised that the effective filling pressure of the heart cannot be determined simply by manometers equilibrated with atmospheric pressure, but that it must be calculated on the difference between pressures inside and outside the right atrium For this reason a differential manometer which provided the algebraic sum of venous and intrathoracic pressures was used

Material and Methods

(1) 6 healthy people and 2 patients with severe emphysema were studied lying flat A 24 lb lead weight with a surface area similar to that of the hand was placed on the abdomen, and the intrathoracic and intra-abdominal pressures were measured simultaneously

These measurements were obtained from water-filled open-ended plastic tubes in the œsophagus and stomach (Dornhorst and Leathart 1952) and recorded with capacitance manometers ('Minirack,' Southern Instruments Co) The reference point was 10 cm above the table Changes in chest circumference were recorded from a mercury-filled rubber-tube stethograph of the type described by Wade (1954) A simultaneous spirometric record was obtained by incorporating a potentiometer in a Benedict-Roth spirometer These four parameters were recorded simultaneously on a four-channel photographic recorder (Elmquist)

(2) 7 healthy people, 2 asthmatics with a normal circulation, and 14 patients with heart-disease (7 of whom had venous hypertension) were studied lying flat.

Intrathoracic pressure was measured through a water-filled polyethylene tube, about 100 cm long and 1 mm in internal diameter, passed through the nose into the œsophagus (Dornhorst and Leathart 1952) An identical tube was used to measure venous pressure so as to reduce differences in damping to a minimum This was introduced into the basilic vein of the left arm either through a needle or, under direct vision, through a small incision The tube was advanced to a distance previously determined by a surface measurement until the pressure record on the oscilloscope showed a response to coughing similar to a simultaneous œsophageal pressure record Then it was assumed to be in the superior vena cava

Pressures were recorded with capacitance manometers One of two reference points was used—either the sternoclavicular joint or the "phlebostatic axis"[*] (Winsor and Burch 1946)

---

[*] The 'phlebostatic axis' is the line of intersection between a plane drawn through the mid axillary line and a plane passing at right angles to this at the level of the fourth intercostal space at the sternal edge

The reference point and the anteroposterior diameter of the chest are recorded with each figure A single 25 cm column of saline solution was used as standard for both manometers

The manometers recording central venous and intrathoracic pressure were used in conjunction as a differential manometer, the electrical output from one manometer being opposed to *that of the other (Lee et al 1954) Thus was arranged so that* the differential record—the "filling pressure"—was positive when the venous pressure was higher than the œsophageal pressure The two direct pressures were monitored on a cathode-ray oscilloscope and recorded together with the differential pressure and an electrocardiogram by a four-channel photographic recorder

Because it is difficult to maintain a constant pressure with the hand, the lead weight already described was placed centrally on the abdomen This particular weight was chosen because the subjective sensation was similar to that produced by compression with the hand of the physician attempting to demonstrate reflux Hultgren (1950), however, considered that a 15 lb weight approximated to the pressure with the hand

Results

Effect of Application of Weight on Breathing

When a weight was applied to the abdomen, the intra-abdominal pressure always rose The effect on intrathoracic pressure was variable not only from one person to another but also with repetition in the same person If the subject "accepted" the weight, without abdominal resistance, the chest had to take over some of the diaphragmatic share of ventilation Fig 1A shows that this new type of breathing, shown by the spirometer, was achieved by increasing the chest circumference The unchanged intrathoracic pressure indicated that the increase in chest circumference had compensated for the reduction in chest volume which resulted from the ascent of the diaphragm (shown radiographically by Lian and Blondel 1925) If the subject resisted, the weight was supported partly by descent of the diaphragm (fig 1B) The chest circumference was unchanged, the intra-abdominal pressure rose higher than in fig 1A, the intrathoracic pressure fell, and the spirometer showed that the intrathoracic volume had increased considerably

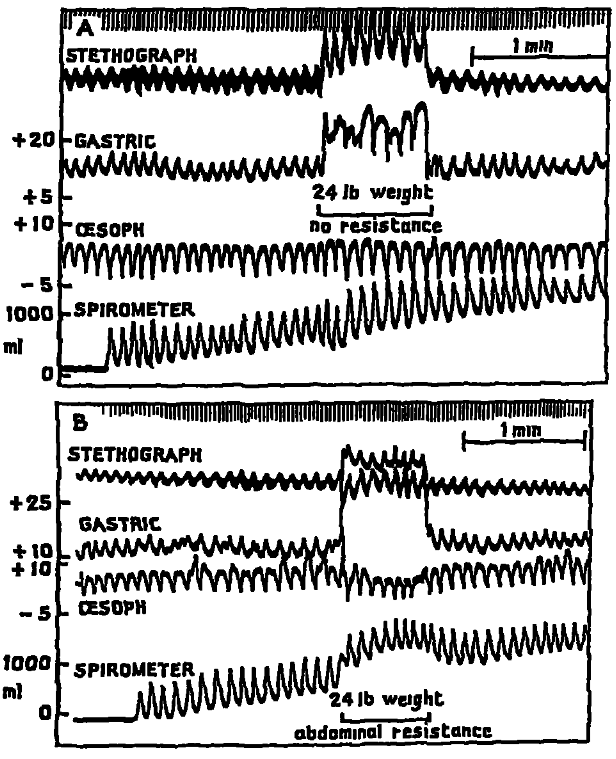

Fig 1—Simultaneous records obtained in healthy person during application of weight to abdomen A, without abdominal resistance; B, with resistance Note that in B gastric-pressure tracing crosses stethographic tracing during application of weight Reference point 10 cm anterior to back; anteroposterior diameter of chest 24 cm *Standards in cm saline Time marker lines, 2 sec*

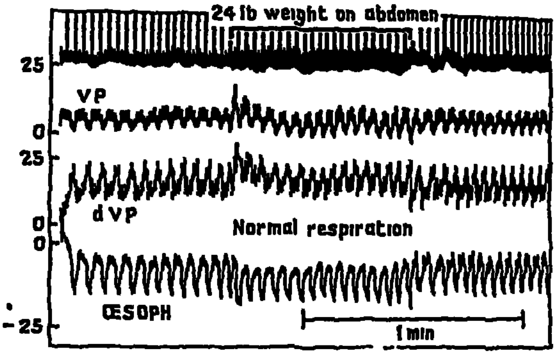

Fig 2—Healthy person: (from above downward) time marker (2 sec), electrocardiograph, V P, central venous pressure, dVP, differential or filling pressure; Œsoph, œsophageal pressure, as intrathoracic pressure *Reference point sternoclavicular joint; anteroposterior diameter of chest 20 cm*

It was impossible to predict the subject's response when no instructions were given about what he should do If the weight caused discomfort, he would resist If it did not, he tended to resist less with repetition as he found that breathing was easier if it did not involve moving the weight—i e, if it was more "thoracic" than "diaphragmatic" If instructions were given that he should not resist the weight, better repeatability was found, but even then there were significant variations in the results The chief relevant effect of resisting the weight is that it increases the pressure gradient across the diaphragm, which encourages the transfer of blood from abdomen to chest

In the 2 patients with emphysema the results were different Whether the patient resisted the weight or not, the effect of its application was to raise intrathoracic pressure In a further study of 7 patients with emphysema the intrathoracic pressure alone was recorded during the application of the weight to the abdomen The intrathoracic pressure rose considerably in 3, slightly in 2, and not at all in the remaining 2 In severe emphysema the chest is nearer the position of full inspiration throughout the respiratory cycle than it is in a healthy person The patient is therefore deprived of a mechanism for keeping the intrathoracic pressure at its resting level by further expansion of the chest In the 2 patients in whom the intrathoracic pressure remained unchanged the chest was probably capable of further expansion to compensate for the ascent of the diaphragm

Effect of Application of Weight on Central Venous and Filling Pressures

Normal—When the weight was applied to the abdomen in the 5 healthy people, there was a transient rise in venous pressure This rise was usually of short duration—e g, through three respiratory cycles (fig 2) *However,* there were minor variations which were due mainly to variations in the type of breathing response The venous pressure may even fall during the application of the weight if the subject breathes purposefully nearer his inspiratory maximum than normally There was then a greater than normal rise in filling pressure, reflecting the greater increase in venous return that results from the greater pressure gradient across the diaphragm The central venous pressure, however, fell after an initial small rise During the same type of breathing but without the application of the weight, the filling pressure still rose and the central venous pressure fell The initial peaks in both the central venous and filling pressures were lacking, indicating that application of the weight produces reflux of blood from the abdomen to the chest As already stated, the response altered with repetition However, to assess the situation accurately in any one person it would be necessary to have a simultaneous record of spirometer, stethograph, intra-abdominal pressure, intrathoracic pressure, and central venous and filling pressures Technically this was beyond our means

A fall in central venous pressure during the test was only seen in healthy people deliberately breathing near their inspiratory maximum The fall was then attributable to the fall in intrathoracic pressure The filling pressure always rose, usually for a short time

Cardiac failure—With heart-failure the extent and duration of the rise in venous pressure was greater than in healthy people An extreme example is shown in fig 3 In those people whose venous pressure was high at rest the response was similar In a "false negative" result the rise in filling pressure was not reflected in a rise in venous pressure, because the intrathoracic pressure fell There was, however, a gradation from the extreme example shown in fig 3 to the normal response In one patient, who had been orthopnœic and œdematous ten days previously, a normal filling pressure response followed treatment In a patient with mitral and aortic stenosis and a normal venous pressure the abnormal hepatojugular reflux was almost entirely attributable to an accompanying rise in intrathoracic pressure and was therefore a "false positive" Curiously and inexplicably, the only occasion on which we recorded an abnormal rise in filling pressure with a normal resting venous pressure was in an athletic medical student.

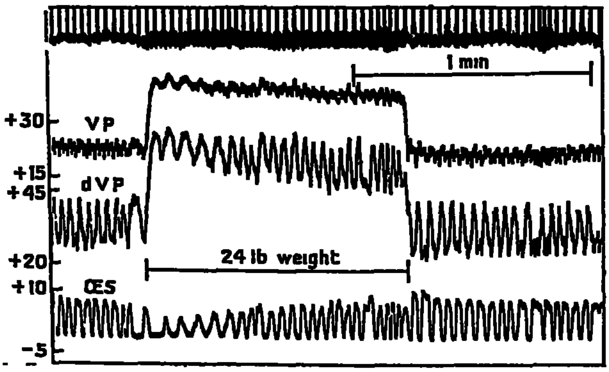

Fig 3—Patient with heart-failure from mitral stenosis Notation as in fig 2 Reference point phlebostatic axis, anteroposterior diameter of chest 16 cm (Artefact restricts troughs of œsophageal record)

The importance of the distinction between filling pressure and central venous pressure is emphasised by the records from a patient with pulmonary valvular stenosis (fig 4) An almost identical rise in central venous pressure was obtained by applying the weight either to the abdomen or to the chest In the first instance filling pressure rose, in the second the rise in central venous pressure was attributable to the rise in intrathoracic pressure, and the filling pressure fell This observation can be repeated at the bedside Most of the patients whose jugular venous pressure rises on the application of pressure to the abdomen show this also if similar compression is applied to the chest, if their breathing continues as normally as possible

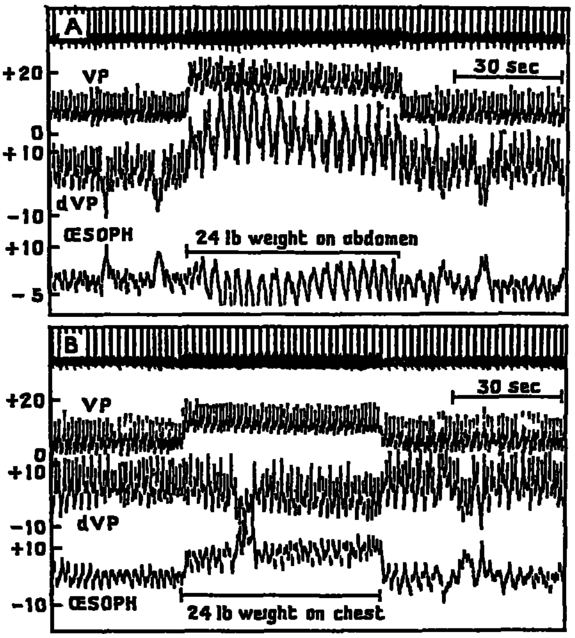

Fig 4—Congenital pulmonary valvular stenosis Notation as in fig 2 Reference point sternoclavicular joint, anteroposterior diameter of chest 18 cm (In B rise in œsophageal pressure, which lasts about 6 sec during application of weight, is due to swallowing and produces negative artefact in differential pressure)

Asthma—In 2 patients with asthma the application of the weight produced no appreciable changes in intrathoracic and central venous pressures In these patients the changes in intrathoracic pressure with breathing was, of course, greater than normal

Discussion

Pressure on the abdomen is one of the standard methods of increasing venous return (Landis and Hortenstine 1950) and is more convenient than exercise, raising the legs, releasing venous occlusion cuffs, while adopting the squatting position or after a Valsalva manœuvre It has, however, numerous disadvantages It is impossible to produce standard pressure with the hand, though Burch (1957) has described a device designed to overcome this objection Even if the pressure is standardised, its effect would be modified by the resistance to the pressure and by differences in the abdominal venous capacity, both in one person on different occasions and between different persons Even if the gross artefact which results from closure of the glottis and a modified Valsalva manœuvre is avoided by asking the patient to continue breathing normally, there is an important variation in the breathing response even in the same person on different occasions The training effect already described might lead the physician to exaggerate the efficacy of his treatment from day to day in a patient with cardiac failure However, patients with cardiac failure, in an attempt to protect the liver from painful pressure, may continue to resist Although one can infer that, if the patient is resisting the hand, it is the descent of the diaphragm which is mainly responsible for the resistance, it is impossible to achieve precision without the simultaneous measurement of at least 6 parameters, which is bound to eliminate the test from clinical practice The test involves a measurement of the jugular and therefore central venous pressure at the bedside, whereas the proper interpretation of the test requires knowledge of the filling pressure—i e, the difference between the pressures within and around the right atrium

Landis and Hortenstine (1950) state "the effects of exercise on venous pressure in normal subjects suggests that the difference between them and patients with overt cardiac failure may be quantitative rather than qualitative" The changes in filling pressure which we recorded during the test lead us to a similar conclusion In addition, the disadvantages already described restrict the value of the test when it is most needed—i e, in detecting early cardiac failure in the absence of other evidence When the reflux, judged by its extent and duration, is clearly abnormal, there is usually more reliable evidence of cardiac failure Some patients had a normal venous pressure after a recent diuresis In such patients a large and sustained increment in venous pressure when the abdomen is compressed may indicate heart-failure

However, when œdema is no longer present, the danger of using a positive hepatojugular reflux to diagnose cardiac failure of which there is no other evidence is emphasised by the findings in the medical student already cited His venous pressure rose 9 cm when a 24 lb weight was applied to his abdomen, and 22 sec elapsed before it returned to its resting level

In patients with severe emphysema abdominal compression raises the intrathoracic pressure This seldom happens in healthy people The simultaneous rise in central venous pressure which results is often taken as evidence of cardiac failure Such an inference is unjustified, because the rise in central venous pressure may be entirely attributable to the rise in intrathoracic pressure which results from the inability of the overexpanded chest to expand further and thereby compensate for the upward displacement of the diaphragm In emphysema a positive hepatojugular reflux may be a more reliable indication that the emphysema is severe than that there is cardiac failure

At present it is by no means universal to measure venous pressure by observation of the internal jugular pulse It is unusual for this to be more than 2–3 cm above the sternal angle in a healthy person In one such person with a venous pressure of 8 cm apprehension appeared to affect the central venous pressure in the same way that it is well known to affect the arterial blood-pressure There is experimental support for the view that apprehension increases venomotor tone (Duggan et al 1953) In our experiments we found that, with practice the clinical method showed good correlation with the direct method described The accuracy of this method largely eliminates the need for the test of hepatojugular reflux

Measurements of the venous pressure from the antecubital vein have shown normal figures to lie between 50 and 140 mm of water above the phlebostatic axis (Winsor and Burch 1946) However, Pedersen (1952) has shown that there is a wide variation in the extent to which the pressure in an antecubital vein is higher than the central venous pressure,

It is a common experience of those who frequently use this method that the venous pressure may be 6 or 7 cm when the external jugular veins are empty, and it is for this reason that this method proves more reliable in practice than the more widely known of Lewis' methods using the external jugular vein, investigated and favourably reviewed by Borst and Molhuysen (1952)

Lewis (1946) concluded that the hepatojugular reflux is "sometimes useful in estimating the amount of blood which is held in the abdomen and in helping to determine the size and position of the cervical veins" Our conclusion is that the only certain value of the manœuvre is in distinguishing a venous from an arterial pulsation in the neck when this is difficult When the internal jugular veins are being used as manometers, it is convenient to be able to raise the column so easily in establishing the normal resting level

Summary and Conclusions

The mechanism of the hepatojugular reflux was investigated in healthy people, in patients with cardiac failure, and in patients with emphysema The prime object was to assess the value of the test as an early sign of cardiac failure

During the test the intra-abdominal pressure rose, and the intrathoracic pressure either rose, remained steady, or fell In most of the patients with emphysema the intrathoracic pressure rose

The filling pressure (the algebraic sum of the intrathoracic and central venous pressures) rose in all the subjects, being highest in those with cardiac failure The variation from the normal was quantitative rather than qualitative The effect on central venous pressure was largely determined by the simultaneous change in intrathoracic pressure Since this was unpredictable, it was concluded that observation of the jugular venous pressure while performing the test of hepatojugular reflux is unreliable as an early sign of cardiac failure In emphysema the intrathoracic pressure response was more predictable and the jugular venous pressure could be expected to rise, but this does not necessarily indicate cardiac failure

The test is of value in identifying venous pulsations in the neck

We are grateful to Dr R W D Turner for his cooperation, Dr E B French and Dr W E Medd for helpful criticism, colleagues, students, and patients who were the subjects under investigation, Mr J A Ramsay, who made the differential manometer, and Miss Norma Millar for technical assistance This research programme has been supported by a grant from the Scottish Hospitals Endowment Research Trust

DURATION OF NIGHT FEEDING IN INFANCY

JANET R CAMPBELL
M B Glasg , D P H
DEPUTY AREA MEDICAL OFFICER, AREA 2,
MIDDLESEX COUNTY COUNCIL

THE length of time that an infant on " demand feeding " requires to be fed at night is an important issue to the mother longing for an undisturbed night's rest

In an attempt to answer this question the eight medical officers* in charge of infant-welfare centres in Area 2 of Middlesex County Council (Southgate, Wood Green, Friern Barnet, and Potters Bar) recorded the birthweight, place of birth, and method and hours of feeding of every infant aged up to about 6 months attending their centres

" Demand feeding " is the accepted method of infant feeding throughout the area and is encouraged by all the medical officers and health visitors at the centres In practice this means that the babies are fed about every three or four hours, but occasionally the intervals may be either shorter or longer according to the baby's demands

Night feeding seems to stop fairly suddenly Typically the baby sleeps through the night two or three times one week and next week or the week after no longer demands night feeds

The mothers say that babies who have never had a night feed have slept through the night from about 10 or 11 P M until about 5 or 6 A M from birth

The end of night feeding was reckoned from the age at which the baby went without one feed at night and so reduced by one the number of feeds it had in twenty-four hours

The survey showed no significant difference between bottle-fed and breast-fed babies or between those born at home and in institutions The important factor was birthweight The accompanying table shows the relation between birthweight and duration of night feeding

(1) In group A 9% and in group D 29% never had a night feed

(2) In group A 27% and in group D 52% had ceased night feeds by the age of 4 weeks

(3) In group A 62% and in group D 81% had ceased night feeds by the age of 2 months

(4) In group A 91% and in group D 89% had ceased night feeds by the age of 3 months

By the age of 3 months the birthweight had ceased to influence the issue

RESULTS OF SURVEY

Group	Birthweight (lb)	No of babies	No night feed	None after 4 weeks	None after 2 mos	None after 3 mos	None after 4 mos	Continued after 4 mos
A	Less than 6½	55	5 (*9*%)	15 (*27*%)	34 (*62*%)	50 (*91*%)	51 (*93*%)	4 (*7*%)
B	6½–7	58	10 (*17*%)	24 (*41*%)	42 (*72*%)	50 (*86*%)	54 (*93*%)	4 (*7*%)
C	7–8	90	24 (*27*%)	45 (*50*%)	66 (*73*%)	80 (*89*%)	83 (*92*%)	7 (*8*%)
D	More than 8	63	18 (*29*%)	33 (*52*%)	51 (*81*%)	56 (*89*%)	59 (*94*%)	4 (*6*%)
	Total	266	57 (*22*%)	117 (*44*%)	193 (*73*%)	236 (*89*%)	247 (*93*%)	19 (*7*%)

I have drawn particular attention to the extreme groups A and D It will be noted that groups B and C are entirely comparable

I wish to thank Dr Kenneth Soddy for his interest and help in the survey The work was undertaken with the consent and approval of Dr W C Harvey, the area medical officer, whom also I wish to thank The Middlesex County Council takes no responsibility for any statements contained in this article

ALLERGIC SKIN RESPONSES ABOLISHED UNDER TREATMENT OF ASTHMA AND HAYFEVER BY HYPNOSIS

A A MASON
M B Lond
CLINICAL ASSISTANT
PSYCHIATRIST

STEPHEN BLACK
M R C S
DAN MASON RESEARCH
FOUNDATION SCHOLAR

WEST LONDON HOSPITAL, W 6

THE successful relief of symptoms of various allergic conditions by hypnosis has been widely reported (Doswald and Kreibich 1905, Asher 1956, Fry 1957, Kennedy 1957, Stewart 1957), but few details of laboratory control during treatment of this kind have been published We therefore tested a patient's skin reactions to known allergens during the relief of associated allergic symptoms by hypnosis

Case-report

A housewife, aged 27, with one son aged 4 years, complained of asthma and hayfever from May to July yearly, for twelve years Her only previous illnesses were mumps and measles in childhood Her brother had had asthma, and her son had infantile eczema during the first year of life

In March, 1957, the patient described her condition as incapacitating between May and July Prevented during these months from performing most of her normal duties as a housewife and mother, she became for this period of each year a " chronic invalid " subject to prolonged attacks of respiratory distress, which occurred mainly at night and left her nervous and often exhausted from lack of sleep She would spend whole nights sitting up in a chair " gasping for breath " Even if during the daytime she had temporary relief from this severe respiratory embarrassment, she was, during these months, never without a " blocked nose " and " running eyes ", with occasional itching round the eyes and long bouts of uncontrollable sneezing

For ten years she had been unsuccessfully treated for these conditions with unidentified pills and inhalants and ephedrine gr $^1/_2$ three-hourly, which she had taken fairly constantly from May to July every summer

In the spring of 1956, however, in the eleventh year of her complaint, she was investigated for specific allergies by skin testing with the extracts of various common allergens marketed by C L Bencard Ltd In this way she was found to be sensitive to pollens normally present in May, June, and July the equivalent extracts being designated by the manufacturers B2 (grasses), B3 (trees), and B8 (spring flowers) The effects on the patient were said to be due mostly to B2

After these tests, and before the hayfever season of 1956, according to the history kindly supplied by the manufacturers, she was given " specific hyposensitisation treatment," by injection, and there was some relief of symptoms The skin-test reactions during this period are described as persisting, and tested again in six months (in January, 1957) the patient was still fully sensitive It was then suggested by the manufacturers that another course of hyposensitisation was indicated if she were to be helped again after May of that year The patient, however, refused further treatment of this kind and was referred by her doctor for hypnosis

Examination

In March, 1957, she was in good health, with pulse-rate 76, temperature 98°F, and respirations 20 a minute Her blood-pressure was 120/90 mm Hg Her chest tended generally to a barrel shape, with an unduly obtuse costal angle and prominent costal cartilages, but its movements were full On palpation and percussion nothing abnormal was discovered, but expiratory rhonchi were heard on auscultation anteriorly over the 3rd and 4th interspaces on both left and right sides, although no mention of any "asthmatic attack" had been made The heart sounds were normal Examination of the central nervous system revealed nothing abnormal except slight, but equal, exaggeration of both knee-jerks and failure to elicit ankle-jerks and plantar responses on both sides The blood-picture, otherwise normal, showed a raised eosinophil-count of 10% of the total white-cell count

Treatment

During the last part of March and the whole of April the patient attended weekly as an outpatient to prepare for hypnotic treatment of the asthma and hayfever by the induction of increasingly deep hypnotic trances The method of induction used was the therapist's own modification of the Erickson-Wolberg "hypnosis by means of hand levitation" (Wolberg 1948)

The patient was a good hypnotic subject and responded quickly to the various routine suggestions by which deeper trances were achieved By the end of April she could be put into a profound hypnotic trance in two or three minutes after lying down on the couch A week before the usual date for the beginning of the patient's yearly attacks direct hypnotic suggestions were made for the first time about her symptoms She was told that this year she would have neither asthma nor hayfever, the therapist concentrating largely on the symptoms previously described by the patient She was told "This year you will have no difficulty with your breathing, either at night or during the day time" and "This year you will not have a blocked nose, your eyes will not run, there will be no itching round your eyes, and you will not have sneezing attacks" Direct suggestions were also made about her sensitivity to pollens and other substances in the atmosphere, and she was told that now she would no longer respond to their presence with "the symptoms of asthma and hayfever"

It is important to note, however, that at no time was any mention made of the extracts of allergens to which she was known to be sensitive, or of any skin tests, or of the results of any such tests made either during this time or on previous occasions

Result

Such treatment, lasting on each occasion up to thirty minutes, was given weekly from April 29 to July 8, and during the whole of this period the patient remained well and, according to her own account, was for the first time in twelve years at this season completely free from any of the symptoms of either asthma or hayfever After a "cold in the head" contracted during the second week in June, she felt on the night of June 15 that "an attack of asthma might be coming on", and she therefore took ephedrine gr $^{1}/_{2}$ and repeated the dose the next morning No asthma developed, and this was the only pharmacological treatment for her usual complaint taken by the patient in the whole season, during which previously she had constantly taken drugs for eleven years

Experimental Methods and Materials

To test the patient's skin reactions during this treatment, weekly skin tests were made with the commercial extracts of the three allergens to which she was known to be sensitive and a control On each occasion the results were measured in terms of the areas of urticarial reaction in sq mm recorded fifteen minutes after testing

To standardise the area of skin involved in each test an aluminium shield, curved to fit the flexor aspect of the patient's arm, was prepared with four holes, 2 mm in diameter on the inside and countersunk on the outside In the tests a separate hole was used for each extract and the control, and one drop, delivered by a single application of the plastic dipper supplied in each bottle of extract, was placed on the skin revealed by the hole in the shield (about 3 sq mm) Multiple pressure through the drop was then exerted ten times, without scratching, with a sterile hypodermic needle A fresh needle was used for each allergen, and the different test sites were identified on the patient's arm by marking in ink with a ball-point pen, care being taken to avoid the test areas

As a check on the effects of different degrees of pressure with the needle—obviously not fully standardised by this means—a comparison was made between the responses due to very light pressure and actual skin punctures made ten times through drops of the extract B2, to which the patient was known to be most sensitive The results of different degrees of pressure over equal areas, assured by the aluminium shield, were about equal

The control fluid, supplied by the manufacturers as allergically inert, was also tested Ten pricks through this fluid, compared with identical treatment of a dry area, gave exactly the same "triple response" reaction (Lewis 1927) and no urticarial weal of any kind

To record results a length of $1^{1}/_{2}$-in -wide 'Sellotape' was placed over the line of test sites fifteen minutes after testing The outlines of the areas of urticaria were then inked with a ball-point pen on the sellotape, which was afterwards removed

To estimate the area involved in each test response and to make accurate comparisons, the outlines on sellotape were subsequently transferred in the laboratory on to lead foil (taken conveniently from the back of old dental X-ray films) These areas of lead foil were then cut out with scissors and a scalpel, and the resulting pieces were weighed Since 1 sq cm of this foil weighed 36 mg, the area of each urticarial weal could be calculated The uniform thickness of the foil used was checked by weighing equal areas cut at random from different parts, and any variation was estimated to be within the limits of experimental error involved and was not significant

The tests were usually made on the flexor aspect of the patient's left arm, with a preliminary test before treatment on the first occasion on April 29, but after treatment on subsequent occasions up to nine weeks At weeks 4, 5, 8, and 9 unexpected tests were also made on the left leg, the aluminium shield being applied to the medial aspect of the thigh At the 10th week the test was made before treatment, and at the same time blood was taken by venepuncture in order to estimate the Prausnitz-Kustner reaction (Prausnitz and Kustner 1921) in a non-allergic volunteer

Results

At the beginning of the course of treatment the patient responded to the allergens B2, B3, and B8 but not significantly to the control She was most responsive to the extract B2 (grasses), an urticarial weal developing in fifteen minutes to 361 sq mm, compared with 72 sq mm for B3 (trees) and 50 sq mm for B8 (spring flowers) The response to the control on this occasion was 33 sq mm of erythema without any evidence of a true urticarial weal such as attended every response to the allergen extracts

Tested after treatment during the following weeks, however, the reactions on the left arm seemed to reflect the improved condition of the patient's health, the skin responses to all three extracts decreasing steadily each

TABLE I—ALLERGIC SKIN RESPONSES DURING HYPNOTIC TREATMENT SHOWING AREAS OF URTICARIA IN SQ MM

Left leg				0				0		0		

week and reaching zero together for the first time after the seventh treatment, but these results did not apply to the occasional unexpected tests on the left leg, which at weeks 4, 5, and 8 gave wide areas of urticarial response, in spite of what was happening to the left arm

At the 9th week, therefore, the procedure was changed and, while the patient was in the hypnotic trance, an additional and direct suggestion was made that, apart from the general improvement in her health, her skin would afterwards be unresponsive to tests with the three extracts anywhere on her body Tested immediately on waking there was no urticarial reaction at all to any of the extracts or the control, on either arm or leg

With the patient now consistently free from both asthma and hayfever, and from any skin responses when tested with the known allergens, an attempt was made to elicit the Prausnitz-Kustner reaction in a non-allergic volunteer At the 10th week of treatment, therefore, the patient was skin-tested before treatment and found to be still completely unresponsive to all three extracts and the control Blood was then taken by venepuncture and serum extracted by centrifuge About 0 1 ml volumes of this serum were then injected intradermally at four points on the flexor aspect of the volunteer's right arm

TABLE II—PRAUSNITZ-KÜSTNER REACTION IN VOLUNTEER

Extract	Prausnitz-Kustner reaction (sq mm.)	
	Left arm	Right arm
B2	0	69
B3	0	36
B8	0	0
Control	0	0

The volunteer was next skin tested on the left arm with the three allergen extracts (B2, B3, and B8) and the control, and readings were taken in the usual way after fifteen minutes There was no reaction At thirty minutes after the intradermal injection of the patient's serum, further skin tests were made over the injection sites on the volunteer's right arm with the same allergen extracts (B2, B3, and B8) and the control Whereas there was now no response to the control or to B8, urticarial weals appeared at the sites of application of B3 (36 sq mm) and B2 (69 sq mm) and remained present for twenty-four hours

These results are shown in tables I and II

Discussion

An allergic causation of the patient's asthma and hayfever had been previously established and, in spite of fairly successful hyposensitisation the year before, she was still sensitive to extracts of the three known allergens She was now treated by direct suggestion under hypnosis, and for the first time in twelve years she was completely free from the symptoms of her yearly illness After each weekly hypnotic treatment during this time she was skin-tested on the left arm with the allergen extracts involved, and the responses to these decreased over 7 weeks to zero

But the left arm—the routine testing site—was apparently associated at a cerebral level with the relief of symptoms, for periodic unexpected tests on the left leg showed no significant change in the urticarial reaction, which was considerable When, however, the direct suggestion was made that the patient's skin everywhere would be unresponsive to the three allergens, there was no response in either arm or leg Nevertheless, with the patient now free from both symptoms and skin reaction, it was still possible to produce the Prausnitz-Kustner reaction in the skin of a volunteer normally insensitive to the allergens

Thus the symptoms of the physical illness had been relieved by psychological treatment, although the patient's blood still contained the serological basis of her previous hypersensitivity in the form of passively transferable antibodies or atopic reagins (Coca and Grove 1925) By direct suggestion under hypnosis, it had been possible to establish an overriding psychic system of control, which could not only keep the patient well, but could also inhibit selectively the allergic or atopic reaction in different parts of her body Although presumably central in origin, this control system, because of its powers of selectivity, might be assumed to act peripherally—possibly at some stage in the local process initiating the *release* of histamine, or other endogenous smooth-muscle stimulants such as acetylcholine or 5-hydroxytryptamine (Lewis 1927, Humphrey and Jaques 1954) Inhibition of tissue *response* to these substances is an alternative explanation In either case, neural rather than humoral communication seems to be implied

Laboratory control thus produced results which supported the general clinical observation that three factors may be involved in the ætiology of asthma and hayfever foreign proteins, sensitised tissues, and a psychogenic factor in no way understood In the present case at least the psychogenic element was further shown to be the most powerful of these three, possibly explaining why psychological treatment in the form of suggestion under hypnosis had provided complete relief from symptoms, where other methods of treatment had proved only partially successful

Summary

A patient with a long history of allergic asthma and hayfever was relieved of her symptoms by hypnotic treatment Weekly skin tests showed her decreasing sensitivity to the known allergens When finally the patient had no symptoms or skin reactions, intradermal injection of her serum into a non-allergic volunteer made it possible to demonstrate the passive transfer of the skin sensitivity to the original allergens (Prausnitz-Kustner reaction)

We wish to thank Dr A. Spencer Paterson for his encouragement and for the facilities granted in the Psychiatric Department of the West London Hospital

AUTOIMMUNISATION IN SUBACUTE THYROIDITIS

ASSOCIATED WITH EVIDENCE OF INFECTION BY MUMPS VIRUS

D Felix-Davies
M D Lond , M R C P

SENIOR MEDICAL REGISTRAR, QUEEN ELIZABETH HOSPITAL, BIRMINGHAM, AND UNIVERSITY RESEARCH FELLOW, UNIVERSITY OF BIRMINGHAM

Subacute thyroiditis was first described as a clinical entity by de Quervain (1904) The original description was confirmed and amplified by de Quervain and Giordanengo (1936), but subacute thyroiditis has, until the past few years, been considered rare The recent increase in frequency of reported cases is probably partly due to more general recognition of its characteristic symptoms and signs and partly to the use of newer aids to diagnosis such as radioiodine and needle biopsy of the thyroid gland There may also be a true increase in incidence as shown by the reports from the Cleveland Clinic, where 27 cases were diagnosed in 1936–45 and 38 cases in 1946–49 (Crile and Rumsey 1950)

For several years subacute thyroiditis has been suspected to be due to a virus (Crile 1948, Fraser and Harrison 1952), but this remained hypothetical until the mumps virus was incriminated in cases reported from Israel (Eylan et al 1957) A positive complement-fixation test using Lederle mumps viral antigen was found for mumps virus in 10 of 11 cases, in 2 the virus was cultured from the thyroid tissue The findings only applied to that particular outbreak, which coincided with an increased incidence of classical mumps The same virus has been incriminated in the case of subacute thyroiditis reported here, which apparently complicated primary thyrotoxicosis

A further feature was the development of antibodies to extract of human thyroid similar to that recently found by Roitt et al (1956) in Hashimoto's thyroiditis This production of anti-thyroid antibodies is of considerabe theoretical interest in that it was in the present patient a temporary phenomenon which later regressed spontaneously

Methods

Radioiodine studies were made with ^{131}I 15 μC, the amounts taken up by the thyroid gland being determined at 24, 48, and 72 hours

Hæmagglutination-inhibition tests for mumps-virus antibody were made by Dr George Belyavin, of University College Hospital, using Enders strain mumps-virus antigen

The antibody titre of the patient's serum against thyroid hormone was estimated by Dr Deborah Doniach and Dr I M Roitt by a modified Oudin technique using as antigen "purified" thyroglobulin 5 mg per ml Similar tests were made by me using as antigen pooled saline extracts obtained from thyroid glands removed post mortem No significant differences in antibody titre were obtained with the two antigen preparations

Complement-fixation tests were made using as antigen the same saline extract of pooled post-mortem thyroid glands 0 25 ml of the patient's serum was inactivated and incubated at 37°C for half an hour with 0 25 ml of antigen and three hæmolytic doses of guinea-pig complement 0 25 ml of a hæmolytic system containing 3% sensitised sheep cells was added, and the tubes were examined for lysis after a further hour's incubation at 37°C Both the antigen and the serum were put up in several dilutions

The serum-gammaglobulin was estimated by paper electrophoresis (Hardwicke 1954)

Case-report

A housewife, aged 43, was first thought to be unwell in March, 1956, by her family, who observed restlessness and prominent eyes In June, 1956, she began to feel ill and to lose weight and noticed that her eyes had become sore and seemed to protrude She became emotionally more labile and subject to mild depression In mid-October, 12 days before admission, stiffness and soreness of her neck muscles developed, and a transient rash appeared on her chin Her throat became sore, and she became increasingly pyrexial, her illness then being diagnosed as primary thyrotoxicosis complicated by pharyngitis Despite treatment with aspirin and sulphadiazine the malaise, pyrexia, and soreness of her throat and neck muscles increased, and she was admitted on Oct 24, 1956, having lost 28 lb in weight in 6 months She had not had any abdominal pain or tenderness or swelling of her salivary glands

Previous history—She had undergone tonsillectomy at the ages of 4 years and 12 years She had never had mumps There had been an increased incidence of mumps in the local schools over the 6 months before her admission to hospital

Family history—There was no recent infectious fever in the family Her two children, aged 10 years and 13, had had classical mumps several years previously A brother with primary hypothyroidism had been maintained on thyroid extract since infancy No anti-thyroid antibodies were found in his serum by the precipitin technique or the tanned red-cell agglutination technique (D Doniach, personal communication)

On examination the patient looked ill and was restless and agitated Her skin was hot and moist She had pyrexia (99°–102°F) and tachycardia (120), obvious eyelid retraction, some exopthalmos, and a fine tremor of her outstretched hands Her pharynx was not inflamed She had a flush over the lower part of her neck and extending to the upper part of her chest, and her skin was warm and hyperæmic Her thyroid gland was tender, both lobes being enlarged, the left more than the right, and the gland felt tense and locally adherent It was estimated to be about twice the normal size No thyroid bruit was audible A small firm non-tender lymph-node lay above the thyroid isthmus, and there were also several small nodes in the posterior triangles of the neck There were no other abnormal signs

Treatment and progress—The patient received no specific treatment apart from mild sedation and intramuscular soluble penicillin G 1,000,000 units twice daily for three days Her malaise rapidly decreased and her temperature and pulse-rate fell to normal within a week Her thyroid gland became less tender and less tense though it was still enlarged Initially the left lobe had been the more affected, but, as this lobe improved, the right lobe became larger and more tender

Initial investigations—Hb 11 9 g per 100 ml , white cells 7000 cm (normal differential count), erythrocyte-sedimentation rate 24 mm in 1st hour (Wintrobe) Chest radiography was normal except for slight lateral compression of the trachea There was moderate proteinuria for the first three days, but the urinary sediment was normal The uptake of radioiodine on the 8th day was 2 7% at 24 hours, decreasing to 1 2% at 48 hours The basal metabolic rate on Nov 8, 1956, 10 days after the remission of pyrexia was −16%

Autoimmunisation—Circulating antibodies to human thyroid extract were found on Nov 11, 1956, at titre of 1 2 of serum

Evidence of mumps infection—A positive hæmagglutination-inhibition test for mumps virus was found to a titre of 1 320 of serum on Nov 11, 1956, decreasing to 1 80 after 26 days, and to 1 40 after a further 31 days

Thyroid biopsy—Biopsy of the isthmus (Mr V Brookes) on Nov 5, 1956, showed that the thyroid gland was bound to

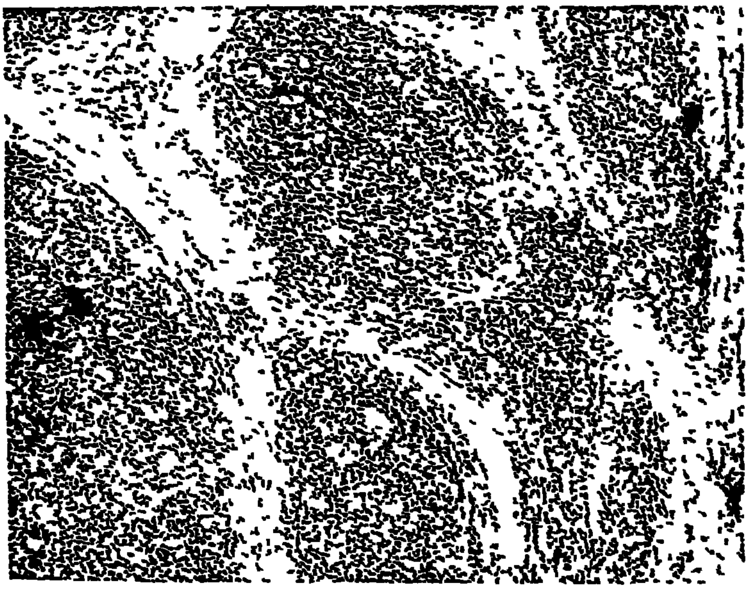

Fig 1—Section of thyroid gland showing interlacing bands of acellular fibrous tissue surrounding areas of surviving parenchyma with heavy cellular infiltration (Hæmatoxylin and eosin. ×30)

the surrounding tissues by adhesions, but not to the extent usually seen in Riedel's chronic thyroiditis The gland felt hard, its surface irregular, and the cut surface extremely firm Histological examination (Dr D B Brewer) showed (figs 1 and 2) the thyroid divided up into demarcated lobules by bands of dense acellular fibrous tissue The lobules, in contrast to these bands of fibrous tissue, were very cellular and consisted of small acini closely applied to one another The outlines of the acini were obscured by a heavy cellular infiltration which was both intra-acinar and interacinar The cells consisted of polymorphs, lymphocytes, and plasma cells, but large intra-acinar giant cells were also present No lymphoid follicles were seen The picture was that of a fairly chronic stage of giant-cell thyroiditis

Further progress—The patient was symptom-free on discharge Her thyroid gland was slightly tender, the right lobe being enlarged and the whole gland easily palpable because of its firm consistence The surrounding lymph-nodes had become smaller Slight exophthalmos and lid retraction were still present Serial studies were made of the clinical state and thyroid function, *and of the changing titre of antibodies to thyroid* extract over the following 11 months (table and fig 3) The patient began to put on weight, and clinical evidence of thyrotoxicosis disappeared except slight lid retraction The thyroid gland remained firm, with a slightly enlarged right lobe The circulating thyroid antibody titre increased over 3 months to 1 16 and then decreased progressively to 1 4 The antibodies were also demonstrated by complement fixation to a titre of 1 40 on Jan 1, 1957, and to a titre of 1 30 on March 21, 1957 Serial serum flocculation tests showed an abnormality which could be correlated with the level of the serum gamma-globulin and the titre of anti-thyroid antibodies (see table) The uptake of radioiodine increased slowly but steadily from 2 7% in 24 hours on admission to 57 9% in 24 hours on Sept 18, 1957 The turnover remained rapid, and on Sept 18, 1957, the uptake in 72 hours had decreased to only 38%, equivalent to a half-life of 3 7 days The basal metabolic rate fell to normal after 3 weeks and has since remained in the normal range, though showing a tendency towards increase (table and fig 3)

Discussion

Diagnosis of Subacute Thyroiditis

The subacute thyroiditis followed a typical course in this patient, with a gradual onset, when pharyngitis was suspected, and later the development of toxæmia, high pyrexia and tenderness of the thyroid gland The tendency for the thyroiditis to affect one lobe and then to subside slowly there but to flare up in the other lobe is well recognised and has led to the name "creeping thyroiditis" Crile and Rumsey (1950) have found that, when the pain, swelling, and tenderness are still confined to one lobe, the uptake of radioiodine may be much depressed, showing that the whole gland is involved

Thyrotoxic symptoms are often present during the acute stage, but the malaise and toxæmia are usually more severe than the degree of thyrotoxicosis would lead one to expect. The duration of subacute thyroiditis has varied in different series, though cases have been reported in which the thyroid gland was tender for more than

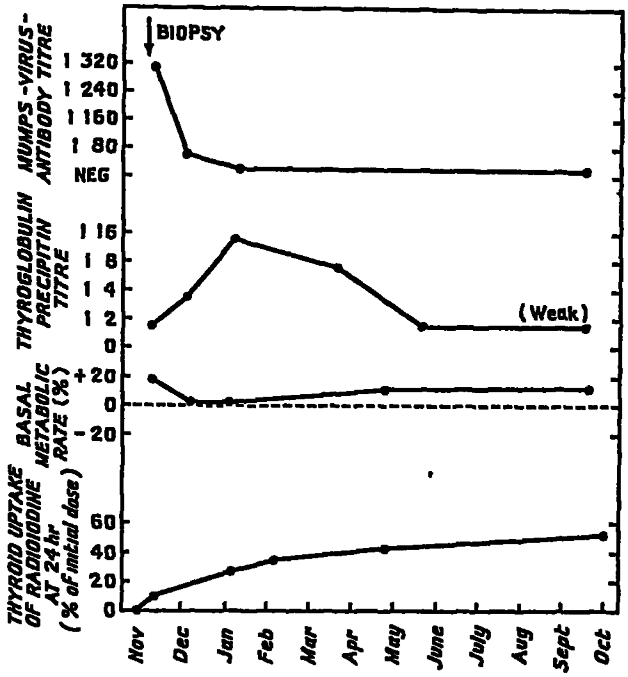

Fig 3—Changes in basal metabolic rate, % radioiodine uptake at 24 hours, titre of mumps-virus antibody, and titre of anti-thyroglobulin precipitin from onset of subacute thyroiditis

a year (Lindsay and Dailey 1954, Stalker and Walther 1951), the duration of acute tenderness for about $2^1/_2$ weeks followed by its gradual decrease over a further 6 weeks, as in the present case, is more usual The clinical diagnosis in this case was confirmed by the histological appearances in the biopsy specimen

Thyrotoxicosis and Thyroiditis

The patient had symptoms and signs of hyperthyroidism for at least 7 months before the acute phase, this suggests primary thyrotoxicosis rather than the insidious onset of thyrotoxic symptoms due to thyroiditis The radioiodine studies after recovery point to a return of this hyperthyroidism Subacute thyroiditis has been followed by thyrotoxicosis within weeks or months on several occasions (Sheets 1955, Perloff 1956), but the history of preceding thyrotoxic symptoms makes it unnecessary to invoke this explanation in the present case Most patients have normal thyroid function after subacute thyroiditis 10 patients followed by Eylan et al (1957) became euthyroid, with a normal uptake of radioiodine, within 6 months and remained euthyroid, this series is particularly valuable for comparison because the thyroiditis was proved to be associated with mumps infection Despite the large number of cases of thyroiditis published to date an association with pre-existing thyrotoxicosis has not been traced Lindsay and Dailey (1954) found no association with any pre-existing disease of the thyroid gland, but Volpe and Johnston (1957) reported 6 cases which followed a simple non-toxic goitre

Evidence for Mumps as Causal Agent

The high level of mumps-virus antibody found by Dr Belyavin during the acute stage of thyroiditis and the fall in titre over the next few months suggested that the thyroiditis was due to mumps virus The possibility of an anamnestic increase in complement-fixing antibody was investigated by Eylan et al (1957) when they first reported their epidemic of subacute thyroiditis, but no such increase was found in other acute fevers The hæmagglutination-inhibition tests made in the present case are probably a more specific index of mumps infection than is the test with complement-fixing antigens, and strongly suggest that the patient had active mumps at the time of the thyroiditis The increased incidence of classical mumps in the local schools over the 6 months before the acute thyroid symptoms is of interest

Autoimmunisation and Thyroid Gland

The finding of antibodies to "purified" human thyroglobulin (less than 95% pure) in many cases of Hashimoto's thyroiditis by Roitt et al (1956) has helped to clarify our understanding of the pathological pattern in that disease and has provided a valuable stimulus to investigators of other types of thyroiditis

The precipitin technique is at present the most valuable method of detecting the antibody but it is not very sensitive The agglutination of tanned red cells coated with antigen, a method used by Prof E Witebsky, is extremely sensitive but more difficult and laborious Complement-fixation tests have not yet been fully assessed Complement-fixing antibodies have been found in most cases of Hashimoto's thyroiditis, many cases of spontaneous myxœdema, occasionally in thyrotoxicosis, and rarely in healthy people

Anderson et al (1957) have followed up these positive complement-fixation tests in apparently "normal" hospital inpatients by post-mortem examination of the thyroid gland where possible, and observed changes which appear similar to, but less pronounced than, the changes of Hashimoto's disease, with lymphocytic infiltration, formation of lymph follicles, and loss of many thyroid acini

The finding by Anderson et al (1957) of histological abnormalities in the thyroid glands of "normal" patients with positive complement-fixation tests is of particular interest in view of Thomson's (1957) work on thyroid histology He found areas suggesting an "immunological reaction pattern" in operation specimens of sporadic goitre, thyrotoxic thyroid glands, and one carcinomatous thyroid gland Various insults to the thyroid gland seem able to cause damage to the acini and to release thyroglobulin Probably infection by mumps virus was the insult in the present case, and it is reasonable to wonder whether the severe infiltration by lymphocytes and plasma cells may be a further indication of antibody production and of local immune reaction Possibly some cases of Hashimoto's thyroiditis may have a similar precipitating cause, and the search for viral infection will doubtless be intensified in the future

Transcience of Autoimmunity

The Lancet (1957) suggests that the antigen-antibody reaction once initiated might become self-perpetuating, but the present case shows that this is not inevitable The titre of antibody decreased although the patient was clinically euthyroid with an increasing uptake of radioiodine by his thyroid gland This suggests that the leak of thyroglobulin had been stopped, and possibly indicates that the viral infection was no longer damaging the acina epithelium—a finding which would fit in with the decreasing titre of mumps-virus antibody It is fascinating to speculate whether total destruction of the thyroid gland and consequent myxœdema, as in Hashimoto's thyroiditis, could occur in thyroid glands with smaller residual powers of recuperation The incidence of a complicating autoimmunisation in subacute thyroiditis is unknown We have examined 3 further cases of subacute thyroiditis with a positive mumps-virus hæmagglutination test

In 1 a weak antibody titre (1 2) to thyroid extract was found 2 months after the onset of thyroid enlargement, this case is of particular interest because of the absence of thyroid tenderness, the only subjective symptom being slight aching in the neck radiating to below the right ear The uptake of radioiodine was 36% of the total dose at 24 hours despite clinical evidence of thyrotoxicity and a basal metabolic rate of +49%

The 2 other cases were seen 6 and 8 months after the acute stage, no antibodies were detected by the precipitin technique

In the 56 patients described by Volpe and Johnston (1957) no residual permanent hypothyroidism was found, suggesting that if autoimmunisation has developed it had not caused progressive damage to the thyroid gland

Summary

A case of subacute thyroiditis is described which apparently complicated primary thyrotoxicosis

A positive hæmagglutination-inhibition test for mumps-virus antibody in a high titre during the acute stage and decreasing later suggested that the thyroiditis was due to mumps virus

Autoimmunisation to "purified" human thyroglobulin took place after the acute stage and reached a peak 3 months later, after which the amount of circulating antibody gradually decreased

I wish to thank Dr C F Hawkins for permission to publish, Prof J R Squire for much valuable advice and facilities for immunological work, Mr W H Bond for the radioiodine studies, Dr D B Brewer for help with the histology, Dr G Belyavin for permission to use his figures on mumps viral antibody titres, and Dr D Doniach, of the Middlesex Hospital Institute for Clinical Research, London, for the initial immunological investigations and much valuable information

ADDENDUM

This patient is mentioned by I M Roitt and D Doniach in a table about thyroglobulin precipitin reactions in other thyroid diseases (*Proc R Soc Med* 1957, 50, 960) Further follow-up studies in February, 1958, show that antithyroid antibodies are now detectable only in undiluted serum

"Dr Wilks said he could not speak too strongly in denunciation of the old fashion, the plan of treating hysteria by physic instead of by moral [psychotherapeutic] means, a plan which was known to be useless, and was yet followed as a matter of routine He had, he said, often reflected with surprise upon a remark made by so intelligent a man as the late Dr James Johnson, who, when called to visit a girl who had been in bed with various hysterical affections for five years, and who had been drenched with gallons of physic, inquired if every 'stinking thing' in the Pharmacopœia had been given her, and when answered in the affirmative, declared he could do no more"—Sir Samuel Wilks *Lectures on Diseases of the Nervous System* 2nd ed London, 1883, p 464

INTERMITTENT HYPERPARATHYROIDISM

L G WHITBY
M B , Ph D Cantab
FORMERLY HOUSE-SURGEON, THE MIDDLESEX HOSPITAL, LONDON, W 1

HYPERPARATHYROIDISM should be suspected in any patient with recurrent renal calculi (Albright and Reifenstein 1948, Richardson 1953) This article describes a patient with such a history, and from whom a parathyroid adenoma was subsequently removed, the preoperative biochemical results showed that the adenoma was only intermittently overactive

Case-report

A woman, aged 50, attended the outpatient department in April, 1956, having had an attack of renal colic 5 days previously, she had no other urinary symptoms In 1946 she first had left-sided renal colic, this recurred on and off till 1948, when a left pyelolithotomy was performed In 1951 she underwent left nephrectomy because of stones, and in 1953 she had a right pyelolithotomy

There were no abnormal physical signs on examination, her blood-pressure was 120/80 mm Hg An intravenous pyelogram (I V P) showed compensatory hyperplasia of the right renal outline excretion was first seen at 5 minutes, and there was dilatation of the calyceal system, in the lower minor calyx there was a moderate-sized calculus and several minute calculi The urine was sterile on culture

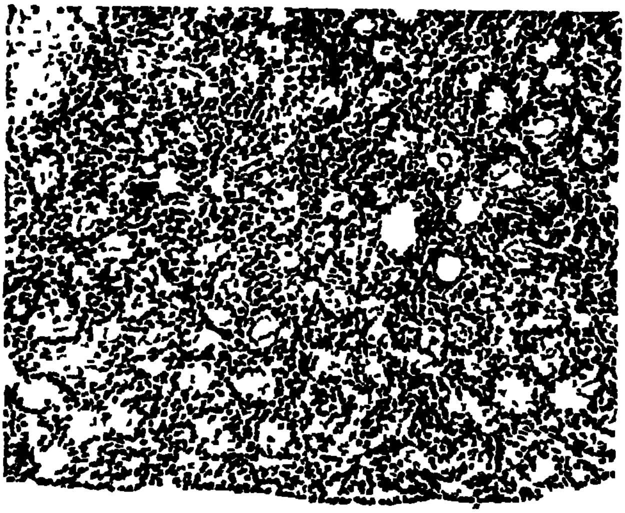
She was admitted to hospital on Sept 7 under the care of Mr C J B Murray, for investigations before the removal of the renal calculus She had had no more attacks of colic An I V P showed that the main calculus had become larger Her hæmoglobin was 74% packed-cell volume 35%, erythrocyte-sedimentation rate (E S R.) (Wintrobe) 10 mm in the first hour, and leucocyte-count 6400 per c mm with a normal differential count The results of biochemical tests are given below

On Sept 30 she had another attack of renal colic, and metabolic investigations were interrupted A retrograde pyelogram on Oct 2 showed that the right renal pelvis contained 60 ml urine, and that the large renal calculus had moved to the upper part of the ureter On Oct 5 Mr E W Riches performed a right pyelolithotomy and partial nephrectomy, the lower pole of the kidney was amputated because it was known to contain minute calculi, one of which could be felt but not dislodged at operation After operation the patient was anuric until Oct 10 (blood-urea 141 mg per 100 ml) During the anuric phase she was treated partly by intragastric drip and partly by intravenous fluids Urine started to drain on Oct. 10, and a urinary fistula developed on Oct 11, the fistula had closed spontaneously by Oct 17 At no time during the anuric or diuretic phases were the patient's serum-electrolyte levels seriously deranged, and they had returned to normal limits by Oct 17

Histological examination of the kidney revealed active chronic inflammatory changes in the calyces with increased submucous fibrosis, and focal inflammatory areas in the renal parenchyma in which there were scanty spherical deposits of calcium

Biochemical tests were resumed at the end of October, and further tests were made when she was readmitted to hospital in November after a period of convalescence The results of these tests are presented in the next section

Mr C J B Murray explored the patient's neck on Nov 28 The biochemical data did not allow of a firm preoperative diagnosis of hyperparathyroidism, and there was no X-ray evidence to suggest the diagnosis, many alternative diagnoses had, however, been excluded, such as sarcoidosis and multiple myeloma At operation the left and right superior parathyroid glands were removed, the left gland was bilobed, measuring 2 × 1 2 × 1 2 cm , and the right was approximately spherical (diameter, 0 6 cm) Her postoperative course was uneventful, with only mild temporary asymptomatic hypocalcæmia



Periphery of the parathyroid adenoma, both clear cells and oxyphil cells are visible (× 120)

Sections of the left superior parathyroid gland showed replacement by an encapsulated adenoma composed of both clear and oxyphil cells, the proportions of the cellular components varied in different areas, and the clear cells tended to be arranged in an alveolar pattern (see fig), the tumour cells were regular in configuration and there was no histological evidence of malignancy The right superior parathyroid gland was histologically normal

The patient was discharged on Dec 7, and an I V P on Dec 28 showed that the right kidney was excreting well She was last seen on Oct 11, 1957, at that time her blood-pressure was 130/80 mm Hg, and a plain radiograph of her abdomen did not reveal any renal calculi

RESULTS OF BIOCHEMICAL INVESTIGATIONS

Period	Date	Blood-urea (mg per 100 ml)	Serum-calcium (mg per 100 ml)	Plasma phosphate (mg per 100 ml)	Urine volume (ml per 24 hr)	Calcium excretion in urine (mg per 24 hr)	Mean urinary calcium concentration (mg per 100 ml)

The table is divided by horizontal lines into four subsections

1 Before pyelolithotomy and partial nephrectomy (performed Oct 5, 1956)
2 After recovery from the anuric episode
3 *Before parathyroidectomy (performed Nov 28, 1956)*
4 After parathyroidectomy

The blood samples were not all taken at the same time of day Figures with F in parenthesis were obtained on samples taken at 8 A M , after the patient had fasted overnight, other blood samples in hospital were taken 2 hours after breakfast

Urine collections were begun at 8 A M *on the dates indicated and* continued for 24 hours The urinary calcium concentrations are overall average figures for each 24-hour period

A calcium-infusion test was performed on Oct 29 1956, the infusion started at 9 A M

Biochemical Investigations

Calcium in serum and urine was estimated by the method of Kramer and Tisdall (1921, 1923) Inorganic phosphate in plasma and urine was estimated by the method of Kuttner and Lichtenstein (1930)

The normal range for serum-calcium is 9–11 mg and for plasma-phosphate 2 5–4 5 mg per 100 ml The normal urinary excretion of calcium is found to be 100–300 mg per 24 hours at this hospital (see also Nabarro 1954), Dent and Hodson (1954) give 120–220 mg per 24 hours as the normal range of urinary calcium excretion, whereas Pyrah (1956) accepts up to 350 mg per 24 hours as normal The normal urinary excretion of phosphorus is 0 5–1 5 g per 24 hours

Many of the results are collected in the accompanying table, which is divided by horizontal lines to correspond with the following four subsections

1 *September, 1956 before pyelolithotomy and partial nephrectomy* —A diagnosis of hyperparathyroidism was indicated by the observation of raised serum-calcium and lowered plasma-phosphate levels However, the urinary calcium excretion on an ordinary diet was 265 mg per 24 hours and, after equilibration on a diet containing 120 mg of calcium per 24 hours, the urinary calcium excretion fell to 159 mg per 24 hours Both of these results are within normal limits (Nabarro 1954), though Pyrah (1956) holds that on a low calcium intake a daily urinary calcium excretion of 150–200 mg per 24 hours is suggestive of hyperparathyroidism The urinary phosphorus excretion was 486 mg per 24 hours and the serum-alkaline-phosphatase was 6 6 King-Armstrong (K-A) units per 100 ml At this time the blood-urea was normal

2 *October, 1956 after recovery from the anuric episode* —On Oct 29 a calcium-infusion test was performed (Howard et al 1953), the load of intravenous calcium was 20 mg per kg body-weight On that day the blood-urea was 29 mg per 100 ml , and the serum-electrolytes were sodium 139, potassium 4 1, chloride 99, alkali reserve 27 mEq per litre *(all within normal limits)*

In the control period before the infusion the patient passed 1495 ml of urine, containing 275 mg of calcium and 482 mg of phosphorus, in the test period these figures were 2500 ml , 482 mg , and 283 mg respectively At the start of the infusion the serum-calcium was 9 8 mg and the plasma-phosphate was 2 1 mg per 100 ml At the end of the infusion the plasma-phosphate was 2 5 mg per 100 ml , and it continued to rise, to 2 9 and 3 4 mg (±0 1 mg) at 4 and 8 hours respectively after the end of the infusion The patient vomited once (150 ml) soon after the *infusion ceased The response to this test was* similar to that described by Howard et al (1953) for normal people

The results of tests in this subsection indicated that the patient's metabolism of calcium and phosphorus was normal, the most significant of these normal results was the serum-calcium of 9 8 mg per 100 ml , supporting evidence being provided by the urinary calcium excretion before the infusion of calcium and by the response to the infusion

3 *November, 1956 before parathyroidectomy* —The results in this subsection are similar to those in subsection I

The serum-calcium had returned to abnormally high levels, and one of the three plasma-phosphate levels was subnormal The urinary calcium excretion ranged from 225–298 mg per 24 hours (mean 265 mg) and the serum-alkaline-phosphatase was 8 K-A units per 100 ml

The *total serum-protein* was 6 4 g per 100 ml (albumin 3 8 g per 100 ml and a normal electrophoretic pattern) The E.S R (Westergren) was 7 mm in the first hour

4 *After parathyroidectomy* —The serum-calcium returned to normal and has remained normal After operation, the daily urinary calcium excretion fell markedly, but it has not been redetermined since discharge from hospital *The plasma-*phosphate was subnormal on March 1, 1957, but was normal on Oct 11 On March 1 the serum-alkaline-phosphatase was 6 6 K-A units per 100 ml

Discussion

Although this patient now only has part of one kidney remaining, her prognosis as far as the recurrence of renal calculi is concerned has been greatly improved The most important effect of parathyroidectomy was to reduce the urinary calcium excretion from 266 mg to 120 mg in 24 hours

The last column in the table shows the urinary calcium concentration, an important determination in patients who have a tendency to form renal calculi The maximum concentration of which a patient is capable can be determined during a calcium-infusion test, it probably shows considerable individual variation (some of Richardson's (1953) patients excreted urine containing 28 mg of calcium per 100 ml without being subjected to a calcium infusion), but, for this patient, the maximum urinary calcium concentration was about 20 mg per 100 ml By increasing her fluid intake (November, 1956) this patient considerably reduced her urinary calcium concentration, and further reduction followed parathyroidectomy

Before parathyroidectomy the biochemical results fell into three clear subdivisions, corresponding to the first three (horizontal) subdivisions in the table In September and November, 1956, hyperparathyroidism was indicated by hypercalcæmia and, on two occasions by hypophosphatæmia Urinary studies did not support the diagnosis, though in retrospect the average urinary calcium excretion of 266 mg per 24 hours should probably have been regarded as abnormal (cf Dent and Hodson 1954), as should the urinary excretion of 159 mg of calcium per 24 hours, after stabilisation on a dietary intake of 120 mg of calcium per 24 hours (Pyrah 1956, McGeown and Bull 1957) By contrast, the results on Oct 28–29, 1956, were strikingly normal, with normocalcæmia and a urinary calcium excretion of 275 mg in 24 hours (which was at that time considered to be normal), followed by a normal response to the calcium infusion test

This pattern of results is most readily explained by the hypothesis that the parathyroid adenoma was only intermittently overactive, being inactive at the end of October, 1956 Such a possibility was suggested by Richardson (1953), though none of his cases demonstrated intermittent overactivity clearly Intermittent hypercalcæmia is mentioned as a pitfall in the diagnosis of hyperparathyroidism by Fraser and King (1957), when discussing why a patient should simultaneously have normocalcæmia, hypophosphatæmia, and hypercalciuria, this triad was shown by this patient in the control period before the calcium infusion (regarding 275 mg of calcium per 24 hours as an abnormally high urinary excretion) The two other possible explanations discussed by Fraser and King for this biochemical triad were induced acidosis (Shohl 1939, Farquharson et al 1931), and idiopathic hypercalciuria (Albright et al 1953), on Oct 29, 1956, the patient's acid-base balance was normal, and she clearly did not have idiopathic hypercalciuria When hypercalciuria and hypophosphatæmia are observed in a patient with normocalcæmia who is not acidotic, Fraser and King (1957) advocate the taking of serial blood samples so as to avoid missing a latent hypercalcæmia

It is impossible to say whether the period of inactivity of this patient's adenoma was spontaneous, or precipitated by the complications that followed pyelolithotomy and partial nephrectomy This case-report, however, shows that the serum-calcium level can fluctuate widely in a patient with hyperparathyroidism, and it shows that, in the absence of other unequivocal evidence of hyperparathyroidism, such fluctuations can endanger the diagnosis

The plasma-phosphate level was subnormal on Oct 29, 1956, and this was the only biochemical test then that indicated a diagnosis of hyperparathyroidism, considering the overall results for that period by themselves It emphasises the value of determining the plasma-phosphate level in routine screening of patients for suspected hyperparathyroidism Hypercalcæmia may be only intermittent, and the observation of a low plasma-phosphate level during a normoclacæmic interval may then be particularly important

Summary

A case is reported of hyperparathyroidism due to an adenoma that was only intermittently overactive Difficulties arise in the diagnosis of intermittent hyperparathyroidism, and plasma-phosphate determinations are valuable in such patients

I am very grateful to Mr C J B Murray for permission to publish this case, and I am much indebted to Dr J D N Nabarro and Mr R T Turner-Warwick for many helpful discussions The histological reports and microphotograph of the parathyroid adenoma were kindly supplied by Dr A D Thomson, and I should like to thank the staff of the Courtauld Institute for the biochemical estimations

TRIPELENNAMINE (PYRIBENZAMINE) IDIOSYNCRASY

H E BELLRINGER
M B N Z
GROUP CAPTAIN, PRINCIPAL SPECIALIST IN DERMATOLOGY TO THE ROYAL AIR FORCE

BECAUSE tripelennamine ('Pyribenzamine') is one of the constituents of a popular anti-histamine preparation commonly prescribed in this country, it is considered that the case reported here may assist in the elucidation of similar diagnostic puzzles Although such cases must be rare, the symptoms are severe, and failure to recognise the condition could lead to tragedy

Case-report

A married woman, aged 49, was admitted to hospital on April 25, 1957, in coma Five days earlier she had complained of suddenly feeling cold, nausea, and then diarrhœa. Since then she had become progressively worse, complaining of pains in her joints and back, severe headache, and loss of appetite A dry unproductive cough and a low pyrexia (100°F) appeared, abdominal pains became severe, and the patient began to ramble mentally

On admission signs of dehydration were evident, and her reflexes were sluggish, but her pupils reacted to light She could not be roused

Treatment and progress —An intravenous saline drip was given, and over the next twelve hours her general condition improved and sphincter control was regained Twenty-four hours after admission she was conscious but confused and disoriented in place and time She took fluids willingly and her diarrhœa abated She had photophobia and severe tenderness over the lower edge of her liver and gall-bladder Clinical, radiological, and laboratory investigations were undertaken to exclude conditions such as acute cholecystitis, infective hepatitis, renal disease, and infection by salmonella All the findings were normal except a relative neutropenia of 6000 white blood-cells per c mm On the third day urticaria appeared on the scalp, arms, and feet and was controlled with 'Antistin' 50 mg four-hourly and promethazine 25 mg at night In spite of help and advice from colleagues no satisfactory diagnosis was made before the patient was discharged after eleven days in hospital

Later developments —Ten days after discharge from hospital the patient was again seen, because the urticaria had recurred severely Chlorpheniramine ('Piriton') was prescribed Late that evening the patient's husband telephoned to say that the nausea, vomiting, and disorientation had returned The patient, unable to obtain piriton immediately, had taken a tablet of tripelennamine-antistin mixture The symptoms began some two hours after ingestion of the tablet It was then learnt that she had been given these tablets, ten days before the onset of the original symptoms, by a surgeon who was treating her chronic rhinitis Subsequently piriton gave the required relief for both the urticaria and the rhinitis without ill effect

Discussion

A previous history of infantile eczema, hay-fever, urticaria, allergic rhinitis, and severe reactions to parenteral and topical administration of penicillin was given The patient had no clear memory of events from the time she was compelled to take to her bed until about twenty-four hours after admission to hospital

In view of the dramatic revelation of the correct diagnosis it was not considered wise to confirm it by further trials of the suspected anti-histamine Antistin had already been given unsuspectingly in hospital, without ill effect, hence tripelennamine remained the likely offender Published reports strengthen this suspicion

Most of the reports of toxic effects from tripelennamine were published in America several years ago, but *The Lancet* (1950) called attention to the dangers of overdosage with anti-histamines Wyngaarden and Seevers (1951) and Sparling (1951) were mainly concerned with the toxic effects of overdosage with tripelennamine and diphenhydramine ('Benadryl') in children That severe toxic reaction does not depend entirely on dosage was noted by Judge and Dumars (1953) and Bunce and Huntley (1953), the former reported delirium, coma, confusion, headaches, and pyrexia among the toxic effects Lott et al (1948) mentioned disorientation, dryness of the mouth, and diarrhœa, and Loveless (1947) shock, urticaria, and neutropenia Judge et al also stated that toxic reactions were commoner in persons with a previous history of allergy They noted that the reactions appeared from two to eight hours after absorption of the drug

Summary

A case of idiosyncrasy to tripelennamine, distinct from toxic effects due to overdosage, is presented

There were severe neurological and gastrointestinal symptoms, with allergic skin reactions

I am indebted to Air Marshal Sir P B Lee Potter, director general of medical services, and Dr R D Darley, of Esher, Surrey, for permission to publish this case, and to Squadron-Leader J S N Mitchell, of the Royal Air Force Hospital, Uxbridge, for the clinical details

HÆMORRHAGIC DIATHESIS DUE TO INCREASED CAPILLARY FRAGILITY SECONDARY TO OVARIAN DEFICIENCY

RONALD WELLS
M B , B Sc Lond , M R C P , D T M & H
From the Department of Medicine, General Hospital, Singapore

THE vascular changes associated with menstruation are probably not entirely confined to the endometrium The fragility of the skin capillaries has been shown to be increased just before each menstrual period and during its first few days (Bickel 1931, Schultzer 1934, Salvatore 1952, Buchholz 1953), and women certainly bruise more easily at these times (Goldburgh and Gouley 1940) A contributory factor may sometimes be premenstrual thrombocytopenia, and cases have been described of thrombocytopenic purpura associated with menstruation (Nagy 1925, Minot 1936)

Some workers have described, under the title " David's disease ", non-thrombocytopenic purpura thought to be due to ovarian deficiency (Wintrobe 1951, Whitby and Britton 1953), but David's five cases ultimately became thrombocytopenic (David 1926), they were all women, but there is little to suggest that they had ovarian deficiency The following case is reported because it seems to be the first in which the relationship between the hæmorrhagic tendency and ovarian deficiency has been clearly shown

Case-report

A European woman, aged 38, was admitted in February, 1957 She had given birth to a live infant in 1947 by a normal delivery, and later had had three miscarriages In 1954 she began to have pain in her right iliac fossa for 2 or 3 days in each intermenstrual period In early 1956 she noticed a lump in the same region, later that year a benign cystic right ovary was removed, the left ovary and uterus appeared normal After this operation the intermenstrual pain ceased, but her next menstrual period resulted in profuse hæmorrhage for 7 days and a brown vaginal discharge for a further 10 days

She sailed from England in December, 1956, and during her second menstrual period after the operation a child on the ship fell on her, hitting her abdomen with its head She immediately had severe abdominal pain and vomiting When she arrived at Las Palmas she had a second laparotomy, and was found to have a small amount of blood in the abdominal cavity and a large band of adhesions matting down the small intestine to the uterus This band of adhesions had two bleeding-points which were ligated, and the intestine was freed from the uterus The left ovary was found to be atrophic

The second menstrual period continued for 3 weeks, and she had to be given a blood-transfusion During this period bruises began to develop on her limbs and abdomen She sailed from

Las Palmas at the beginning of January, 1957, but on the ship soon began to have nausea and severe abdominal pains in the suprapubic and left paraumbilical regions. The colic became very severe and bruises continued to develop.

She was admitted to hospital with severe abdominal colic immediately on arrival in Singapore. The only abnormal physical signs were the operation scars, large bruises on her legs and abdomen, and an internal congenital strabismus of her left eye with suppression of the left visual image. The abdomen was soft and not tender.

Investigation showed a weakly positive capillary-resistance test (Hess test with the cuff at 80 mm. Hg for 10 minutes), hæmoglobin 12.1 g. per 100 ml., white blood-cells 8300 per c.mm. (78% neutrophils, 19% lymphocytes, 2% monocytes, 1% eosinophils), thrombocytes 290,000 per c.mm. The thrombocytes appeared normal in stained dry films and in wet preparations. The bleeding-time, clotting-time, one-stage prothrombin-time, prothrombin-consumption time, clot retraction, plasma-fibrinogen, serum-proteins by electrophoresis, urinary diastase, and serum-amylase were all within normal limits. The urine contained no sugar or ketone bodies, and only a trace of albumin. The urinary deposit was microscopically normal, and the stool contained no occult blood.

Treatment and course.—It was thought that she had a hæmorrhagic diathesis producing bruising and abdominal colic (as in Henoch's purpura), and she was given 200 mg. of cortisone by mouth in divided doses on the 1st day, 150 mg. on the 2nd day, and then 100 mg. daily for a further 23 days. Injections of 40 units of long-acting corticotrophin were given twice weekly to minimise adrenal suppression.

There was no clinical response, the abdominal colic increased and frequent injections of pethidine became necessary to control the pain. Occult blood began to be present irregularly in the stools, and the capillary-resistance test became strongly positive. Repeated investigation showed no significant change in the hæmatological findings. A screening blood-coagulation test, in which the patient's plasma was mixed with varying proportions of normal plasma and was then recalcified at 37°C, showed that the platient's plasma clotted slightly more quickly than normal plasma. There was therefore no evidence of any blood-coagulation defect, and it seemed probable that the hæmorrhagic diathesis was due to increased capillary fragility alone.

The administration of calcium chloride 2 g. intravenously and ascorbic acid 500 mg. by mouth, and the transfusion of 450 ml. of fresh blood, produced no clinical improvement and no change in the strongly positive capillary-resistance test.

Since the hæmorrhagic tendency had become serious only after the removal of one ovary, and since the other ovary had been found to be atrophic, the patient was given a course of oral stilbœstrol in high dosage (40 mg. daily). Her condition gradually began to improve, and by the 3rd day of stilbœstrol therapy it was possible to stop the injections of pethidine. By the 6th day bruising had ceased and the capillary-resistance test was only weakly positive. Stilbœstrol was stopped after 17 days, and within 36 hours the patient again had bruises and severe abdominal colic. Pethidine had to be given again, and the capillary-resistance test became strongly positive. 7 days after the cessation of stilbœstrol therapy dienœstrol 6 mg. daily was started. Once again the bruising and abdominal pain gradually ceased, and the capillary-resistance test became negative on the 3rd day of dienœstrol therapy.

In hospital the patient was observed to have frequent transient losses of consciousness. These attacks ceased when she was given troxidone 900 mg. daily, but after 3 days an erythematous rash developed, apparently in relation to the drug, and administration was stopped. She was then maintained on phenobarbitone 180 mg. daily, and the attacks, which seemed to be petit mal possibly resulting from small hæmorrhages into the cerebral cortex, became much less frequent.

She was discharged at the end of March, 1957, and joined her family in North Borneo. She has continued on dienœstrol and phenobarbitone as above, and up to November, 1957, had only occasional bruises and minor attacks of colic. She still had occasional attacks of petit mal.

Discussion

Under the title "hereditary familial purpura simplex", Davis (1939, 1941) reported eighty-eight cases, eighty-four of them in women, in which there was evidence of a non-thrombocytopenic hæmorrhagic tendency. The bleeding-times, coagulation-times, and clot retraction were normal. Many had positive capillary-resistance tests, and in most cases hæmorrhagic symptoms began around the menopause. Davis found that the condition was common in women, and the present case may be another example of the same syndrome. This case is interesting because there is good evidence that the hæmorrhagic tendency became more evident after oophorectomy and responded to œstrogen therapy. It seems possible that patients with hereditary familial purpura simplex may also respond to this treatment.

In the absence of manifest allergic findings or a suggestive family history, it would be difficult to differentiate Schonlein-Henoch purpura of allergic origin from hereditary familial purpura simplex. Both Schonlein (1839) and Davis (1939, 1941) drew attention to the high incidence of rheumatic symptoms in their respective syndromes, and in both the only hæmatological and vascular abnormality seems to be increased capillary fragility. It seems probable that the two conditions differ only in their ætiology.

The congenital strabismus of the patient reported may be a purely coincidental finding, but the report of seven cases in a single family with increased capillary fragility, six of whom had ptosis (Fisher et al. 1954), raises the possibility of a similar hereditary connection in this case. One of their cases (in a woman, aged 32, with bilateral ptosis and a history of ecchymoses, four miscarriages, and hypermenorrhœa) closely resembles the case reported here.

Summary

A case is described of a woman in whom a hæmorrhagic diathesis developed, owing to increased capillary fragility following oophorectomy; this responded well to œstrogen therapy.

This syndrome resembles hereditary familial purpura simplex, which in turn resembles allergic Schonlein-Henoch purpura.

Hereditary familial purpura simplex may also be found to respond to œstrogen therapy.

This patient was admitted under the care of Prof. G. A. Ransome; I am grateful to him for permission to publish the case, and to Dr. H. Breitkreuz for interpreting the relevant German literature.

Preliminary Communication

HYPERSENSITIVITY TO HISTONE
INDUCED EXPERIMENTALLY IN RABBITS *

An abnormal gamma-globulin has been found in the sera of patients with acute disseminated lupus erythematosus (L E), scleroderma, dermatomyositis, and certain forms of rheumatoid arthritis in which L E cells are present[1] This abnormal protein has been investigated histochemically by the fluorescent antibody technique[2] supplemented by enzymatic digestions and inhibition procedures, and has been shown to possess an apparently specific reactive affinity for intranuclear desoxyribonucleoproteins in autologous, homologous, and heterologous tissues A similar histochemical phenomenon in lupus patients has been described by Friou[3 4]

The constancy of the abnormal gamma-globulin in patients with the listed disorders and the resemblance between the intranuclear binding of nucleoprotein by gamma-globulin and the findings in immune reactions suggest that hypersensitivity to desoxyribose-nucleic-acid-proteins may play a significant role in the pathogenesis of some of the so-called diseases of collagen

To test this we have attempted to sensitise rabbits against heterologous nucleoprotein, in order to establish the immunological state supposed to exist in human patients, and perhaps even to create in animals an experimental disease state similar to, if not altogether identical with, that found in human systemic lupus erythematosis, scleroderma, and dermatomyositis

Methods

Albino rabbits were apportioned at random to groups (table I), each lot containing both males and females The antigen was commercial calf-thymus histone prepared by the method of Mirsky and Pollister,[5] dissolved in 0 2 M hydrochloric acid, and adjusted to neutrality with 1 0 M sodium hydroxide Rabbits in group I received, in addition to the nucleoprotein antigen, an adjuvant based on that of Fischel et al[6] (table II) Each dose contained the same constituents, but they were mixed in different proportions, and with the Fischel adjuvant a different antigen was used

Initial immunisation of the rabbits in group I was attempted by the intramuscular injection of two doses of the antigen-adjuvant combination described Each rabbit in group II was given intravenous histone 50 mg in aqueous solution, and those in group III were injected intramuscularly as their fellows in group I but received adjuvant alone A month later the rabbits were given subcutaneous booster doses of histone 50 mg

All the animals were bled periodically from the marginal ear vein, and their sera were assessed for antibody content by the indirect or "layering" fluorescent antibody technique Tissue substrates included autologous rabbit skin obtained by biopsy under local anæsthesia (procaine hydrochloride 1%), homologous rabbit liver and heterologous bovine aorta secured immediately after death, and heterologous human skin and placenta, obtained respectively at surgery and at delivery Fresh frozen sections were stained with rabbit serum and then counterstained with anti-rabbit gamma-globulin goat-serum conjugate Cross-inhibitions, as described elsewhere (Bardawil et al[7]), were performed between rabbit and human sera Stained sections were examined under a Reichert 'Zetopan' fluorescence microscope and photographed in colour upon 'Super Anscochrome' daylight emulsion with a 'Leica IIII' 35-mm camera with 'Micro Ibso' attachment

Results

Staining Reactions

Of the three animals in group I two died of concomitant infection the first week following injection The surviving rabbit, Adj H-1 (table I), first showed the presence of antibodies to histone 49 days after the initial injection of antigen and about

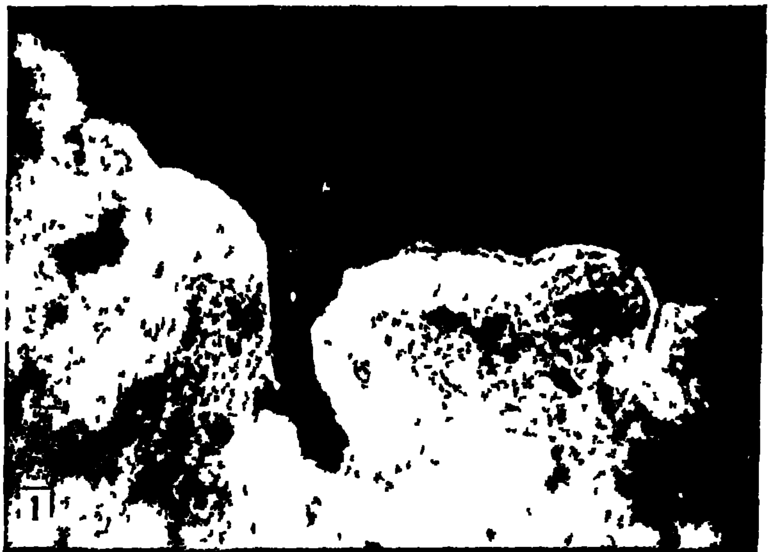

Fig 1—Autologous localisation of serum-gamma-globulin from rabbit Adj H-1 Note nuclear staining within superficial layers of epithelium

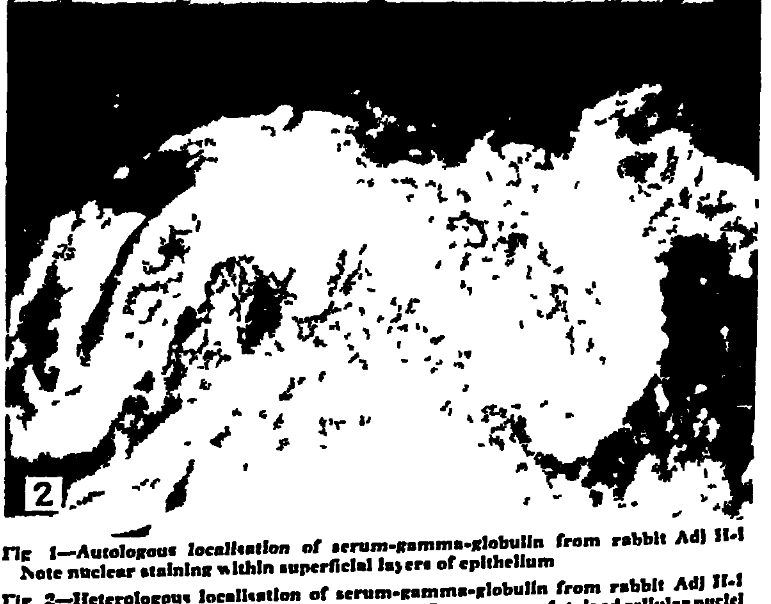

Fig 2—Heterologous localisation of serum-gamma-globulin from rabbit Adj H-1 Human skin as tissue substrate Note brilliant fluorescence of stained cellular nuclei

TABLE I—EXPERIMENTAL GROUPS

Group	Antigen	Rabbit	Result
I	Histone and adjuvant	Adj H-1	Nuclear staining
		Adj H-2	Died
		Adj H-3	Died
II	Histone	H-1	—
		H-2	—
		H-3	Died
III	Adjuvant	C-1	—
		C-2	—

15 days after the secondary dose The antibody level was estimated crudely by the intensity of nuclear staining, and was observed to increase gradually over about 55 days, thereafter declining until staining became weak, irregular, or (as it often did) disappeared A second booster injection, given to this rabbit about 10 weeks after the first, restored the capacity for intense intranuclear staining

Serum-antibodies in the hypersensitive rabbit are bound histochemically with intranuclear material in autologous, homologous, and heterologous tissues (figs 1 and 2) In addition to staining bovine nuclei, from which the antigen had been derived, the serum-gamma-globulin of rabbit Adj H-1 reacted also with rabbit and human nucleoprotein

In group II rabbit H-3 died during the first week after injection Rabbits H-1 and H-2 and the two controls in group III never produced antibodies measurable by the present technique The participation of the rabbits' own gamma-globulin was excluded by direct staining for this protein by techniques described elsewhere [7]

Because a direct conjugate of serum-globulin from rabbit Adj H-1 was not available, auto-inhibition was not attempted

TABLE II—SENSITISING SOLUTION

Dry antigen	50 mg	Aquaphor *	0 2 ml
Tubercle bacilli	0 5 mg	Mineral oil	0 4 ml

Modified from Fischel et al [6]

* Emulsifying agent made by Duke Laboratories Inc.

Serum from this rabbit has successfully cross-inhibited staining by a conjugate made from the gamma-globulin of a patient with active scleroderma

Collateral Tests

At the apparent peak of nuclear staining intensity in Adj H-1, 35 days after the booster injection, a positive Arthus reaction (local œdema and necrosis) was obtained by the intradermal injection of histone 1 5 mg An attempt to induce an Arthus reaction after the capacity for intranuclear staining had waned was fruitless, but an additional intradermal injection applied about a month after the second booster dose caused severe local hæmorrhage and necrosis Attempts to elicit similar responses from the rabbits in groups II and III failed

In attempted ring precipitations, rabbit and human sera were tested against neutral solutions of histone in multiple dilutions The results were inconclusive because both test and control sera precipitated the antigen at practically all concentration levels, perhaps because of the presence of calcium and magnesium cations in the sera

L E -cell preparations made with serum from rabbit Adj H-1 did not show typical inclusion bodies Blood-counts on the sensitised rabbit showed marked anæmia and leucopenia (lymphocytes 70%, segmented forms 29%, basophils 1%)

Discussion

In the surviving test rabbit (Adj H-1) hypersensitivity to histone, induced experimentally, led to the appearance of a circulating serum-antibody with a demonstrable reactive affinity for autologous, homologous, and heterologous intranuclear nucleoproteins The histochemical behaviour of this antibody seems to be morphologically identical with that of the so-called abnormal globulin or "L E factor" reported in human collagen disease The heterophil reactivity observed is to be expected in view of the demonstration by Allfrey et al [8] that desoxyribose nucleic acid from various sources—including calf thymus and kidney, chick erythrocytes, paracentrotus and trout sperm, and wheat germ—can restore to nuclei their capacity for synthesis after it has been destroyed by desoxyribonuclease Though nucleoproteins can mediate the most complex biological functions, they seem to remain sufficiently primitive to be immunologically non-species-specific

If one of the so-called collagen diseases is shown to have a definite basis in hypersensitivity against nucleoprotein, the experimentally noted lack of species specificity may be taken to imply that such allergy in the human patient may follow antigenic stimulation by viral, bacterial, or animal desoxyribonucleoprotein It has been found in this laboratory that positive sera stain ordinary smears of streptococci, including the viridans group Indeed, if a non-specific sensitisation against nucleoprotein is assumed, it is possible to construct a simple and orderly pathogenic theory to account for the classical morphological lesions found in the collagen diseases, embracing not only their character but also their topographical distribution in the body

Demonstration of the intranuclear binding of nucleoprotein is but the first step in the establishment of nucleoprotein sensitivity as a factor in the pathogenesis of some of the collagen diseases The cross-inhibition of serum from a patient with scleroderma provides additional suggestive evidence of a common process The most arduous task of all, that of inducing clearcut clinical disease in animals artificially, has not yet been accomplished

Summary

The histochemical behaviour of sera from human patients with certain so-called collagen diseases has been simulated by samples from an animal sensitised against bovine histone

Evidence is presented that the observed effect depends on immunological reaction, and the relation to human disease is discussed

"The fact that most students attend lectures has repercussions on their lecturers Having a good attendance, teachers may assume that their students must learn a good deal from them, or else they would not attend Accordingly, any lecturer who does not come into close contact with students in laboratory classes, or in other ways, can very well live in a pleasant dream-world about the effectiveness of his teaching Perhaps the easiest and cheapest way to improve university teaching about one hundred per cent would be to make it compulsory for every lecturer to spend a good deal of time with his students immediately after each lecture to find out what they did, and did not, learn from it "—ARTHUR W HAM, *Canad med Ass J* 1958, 78, 482

Reviews of Books

Principles of Gynæcology

T N A Jeffcoate, M D, F R C S E, F R C O G, professor of obstetrics and gynæcology, University of Liverpool London Butterworth 1957 Pp 696 75s

Professor Jeffcoate's new book will be welcomed by the reader who wants more than a standard textbook of factual knowledge In his preface he says that the book is aimed at the undergraduate at the top of the class, but because the emphasis throughout is on the assessment and treatment of the patient as an individual rather than as a case, it could equally well be said that the book is intended for the student who wishes to become a good doctor Description of operative technique is omitted, but symptoms and diagnosis are very fully discussed There are excellent chapters on problems of sex and marriage, hormone therapy, genital cancer, and many other subjects of daily importance to the family doctor The book is essentially practical Short illustrative case-histories and hints from the author's wide experience increase its value

The headings and layout are clear, the illustrations, including twelve colour plates, excellent, and the index comprehensive As a matter of policy no references are given, it is perhaps a pity that a book that so stimulates the interest does not give any guide to further reading and does not provide students "at the top of the class" with brief biographical footnotes about the famous names in gynæcology A few subjects, such as intersexuality, developmental anomalies, and bladder function are described in detail perhaps unnecessarily great for the non-specialist reader They are subjects, however, which have important practical applications and on which much light has been shed by Professor Jeffcoate's own researches and writings

The book can be confidently recommended not only as a textbook on medical gynæcology but also as an excellent thesis on the proper balance between the scientific and the humanistic approach to a subject in which psychosomatic factors are important

Respiratory Disease and the General Practitioner

C M C Toussaint, M R C S, D P H, consultant chest physician, Willesden Chest Clinic and Central Middlesex Hospital, London, president, British Tuberculous Association, 1957–58 London National Association for the Prevention of Tuberculosis and Diseases of the Chest and Heart 1958 Pp 28 7s 6d

This useful handbook deals with the three major respiratory diseases—pulmonary tuberculosis, lung cancer, and chronic bronchitis The sections on pulmonary tuberculosis and lung cancer are excellent essential features have been selected with an unerring eye, and are set out with admirable clarity and conciseness Important points are emphasised by illustrative case-reports and radiographs The only shortcoming is the rather dogmatic approach to the management of pulmonary tuberculosis it seems injudicious, for example, to advocate one year's chemotherapy in preference to a longer period when the general practitioner's adviser on the spot may, possibly rightly, have other views The three pages on chronic bronchitis fall below the generally high standard, but this is nevertheless a splendid little book As a guide to the early diagnosis of pulmonary tuberculosis and lung cancer it could scarcely be bettered, and we warmly recommend it to the general practitioner

Body Water in Man

Maurice B Strauss, M D, professor of clinical medicine, Boston University School of Medicine London J & A Churchill 1958 Pp 286 50s

The title of this book seems to invite comparison with the monograph on Body Water by the late J P Peters, to whom it is dedicated In many ways the book is worthy of this comparison, for it is readable, scholarly, and critical, and manages to illumine a thorough survey of the literature with interesting allusions to comparative physiology There are more non-American references than is usual some of those, as to Homer, Sallust, and the Bible, are no doubt obligatory and pre-Columbian, but others are facultative

The treatment of the subject is centred on physiology, but clinical information is introduced where it illustrates physiological principles This allows a more leisurely treatment of the intake and output of water and salt than is commonly found in similar works The core of the book is an outstanding account of antidiuretic hormone, and the factors which stimulate or prevent its production, adrenal hormones are more cursorily dealt with, and this is perhaps surprising in a book which emphasises volume rather than osmolarity The studies of Wirz on the renal action of antidiuretic hormone are not mentioned, and there is only casual reference to potassium, on which the volume of intracellular fluid largely depends

Although the book does not perhaps fulfil all the title promises, it can be recommended as a critical review of the mechanisms regulating the amount of water and salt in the body

Drugs, Their Nature, Action and Use

Harry Beckman, M D, director, department of pharmacology, Marquette University Schools of Medicine and Dentistry Philadelphia and London W B Saunders 1958 Pp 727 105s

Professor Beckman's new textbook of pharmacology is designed chiefly for undergraduate students The brief opening section, the pharmacologist's apologia, is followed by eight general chapters on drugs and their actions The third section, the major part of the book, deals with individual drugs in much detail, and each chapter or subchapter is rounded off by a useful list of references Those who are familiar with Professor Beckman's writing will look forward to a lively and entertaining book as well as a sound text of pharmacology—and they will not be disappointed Some readers will disagree over details and points of emphasis, but in the main there is very little with which they can quarrel

It is hard to say who will find the book most useful Most medical students in this country would probably consider it both too expensive and too detailed for use as a standard text, but they will find it very helpful when they need a fuller yet concise account of a particular drug, and for this reason it should be in every medical school library Although it is less comprehensive than some other large American textbooks of pharmacology, it could be used with advantage by physicians as well as pharmacologists, they will both appreciate it for its sound common-sense pharmacology and its pleasant and easy style

---

A Woman Doctor Looks at Love and Life (London Macmillan 1957 Pp 190 8s 6d)—Dr Marion Hilliard is the lately retired chief of obstetrics and gynæcology at Women's College Hospital, Toronto, and her book is one of advice to women from adolescence to old age, with a word to husbands, based on her experience of hospital and private practice and of her own (single) life She writes in colloquial Canadian which strikes oddly on the English ear, and the implied social and medical background of urban Canada is strangely different from our own, but there is much wisdom, tinged with humour, in her chapters (that on the menopause is a happy example), and she has an acceptable philosophy—though most things in life are inevitable they can be turned to good account

Connective Tissue (Oxford Blackwell Scientific Publications 1957 Pp 363 42s)—In 1956 the Council for International Organisations of Medical Sciences held a conference in London to expound and coordinate modern views on connective tissue Speakers came from East and West Europe, the United States, and South Africa Nomenclature and chemical methods were much discussed The proceedings have been edited (under the direction of Prof R E Tunbridge, the chairman) by Dr Madeline Keech, Dr J F Delafresnaye, and Dr G C Wood

THE LANCET

LONDON 26 APRIL 1958

The Snows of Yesteryear

To most of us the passions and protestations, the charges and countercharges, the hostilities and heroism of the winter of 1956–57 are mere scraps of memory they have become the raw material of the historian and social scientist It is seventeen months since the first plane-load of Hungarian refugees were welcomed in this country on a wave of popular sympathy Within a few months their number was to increase to 20,000, and they were soon followed by more than 7000 evacuees from Egypt This first phase of the refugee saga was one of crisis and achievement The crisis arose from the need to provide, almost at a moment's notice, thousands of destitute people with shelter, food, and all the basic necessities of life The achievement was the work of voluntary organisations which successfully completed this task These philanthropic bodies, always the butt of the cynical and the sophisticated, have had to face many difficulties in recent years, with the inauguration of the Welfare State even some of their friends questioned their continued value No such doubts remained in the minds of those who observed their work in the last days of November and the early days of December, 1956 That "the rapid success of the Hungarian refugee operation, and the slower but no less praiseworthy achievements in the more difficult task of resettling the Anglo-Egyptians, may be ascribed, above all, to [their] effort" is one of the conclusions in *Refugees in Britain*, a P E P pamphlet[1]

These organisations depended on the generosity of countless individuals, and they benefited from the Government's moral support, but individual charity had to be harnessed, and there was an inevitable time-lag before official organisations began to function During the vital first weeks, while the British Council for Aid to Refugees (the Government organisation set up to cope with the emergency) tumbled from crisis to crisis, the British Red Cross Society and other voluntary organisations were able to call on the immediate services of a highly trained, well-disciplined, and devoted body of workers, and, unhampered by the need to formulate long-term policy, they grappled with the difficulties at hand These included the provision of medical cover at reception stations and in transit camps, the accommodation of the sick in hospital (where interpreters were required even for rudimentary history-taking), and the maintenance of communication between hospital patients and their families While local practitioners and medical officers on loan from the Armed Forces gave first-aid and casualty service, the sudden influx of several thousand apparently fit immigrants raised a formidable public-health problem It is difficult not to sympathise with critics who later deplored that medical cover did not include, from the start, preventive measures, especially radiographic screening for tuberculosis[2], but this was not an act of official ineptitude, nor was it due to lack of foresight by individual medical officers of health It is possible to argue that present-day immigration policy, which takes no account of disease dissemination, is inspired by the ostrich rather than by the spirit of SNOW, but there is no doubt that the official attitude towards the Hungarian and Anglo-Egyptian refugees was in full accord with this policy

The weeks of emergency and improvisation were followed, inevitably perhaps, by a period of disenchantment on the part of the refugees and of frustration on the part of their hosts A striking observation in *Refugees in Britain* is the similarity between the mental reactions of two such widely different groups of people as the Hungarians and the Anglo-Egyptians

> "It might have been expected that the Hungarians would be particularly amenable, being filled with gratitude for the help and generosity of the British people, while the Anglo-Egyptians would be embittered at being expelled from Egypt and insistent on the duty and responsibility of the British Government towards them There were Hungarians who were extremely grateful, and Anglo-Egyptians who were disgruntled, but the distinction is by no means so clear cut"

It took doctors and administrators several months to realise that refugee existence itself imposes on its victims a distinct pattern of behaviour, and the psychological basis of this behaviour is still far from clear Certainly many factors are involved they range from temporary casting-away of certain social inhibitions (an action familiar to every holiday tripper) to complex feelings of guilt towards those left behind *Refugees in Britain* mentions but a few of its manifestations, such as the insistence of many highly educated refugees that behind the ill-advised but well-meant assurance given to them in Austria—that Britain would only be a transit station to America—lay a diabolical ruse to acquire cheap labour This state of mind was often reflected in psychosomatic illness, and it is fortunate that both mental and physical disturbances only rarely left permanent scars

The third phase in the life of the refugees was a gradual return to normality, and this significantly coincided with the recognition by the authorities that the key to resettlement was permanent employment In this respect, says the P E P pamphlet, "the Hungarians were one of the most promising bodies of refugees to arrive in this country" An early check (later confirmed by random samplings) showed that 70% were aged between eighteen and thirty-five, they had not been demoralised by long periods in refugee camps Of nearly 15,000 who had remained in the United Kingdom, only 617 were still registered as unemployed at the end of December, 1957, and only about 1500 (who included dependants, unaccompanied children, and students) had not yet been settled in permanent employment Despite the absence of a language barrier, the permanent resettlement of the Anglo-Egyptians proved a far more difficult task "They were mainly in family groups, many middle-aged or elderly, and usually with a background of commercial and administrative work" Some have refused work because the standard was below what they had been accustomed to some are still delaying in the hope that they may eventually be allowed to return by the Egyptian Government Of the Anglo-Egyptians who had been originally accommodated in hostels 50% were still there at the end of 1957, compared with only 10% of the Hungarians

---

[1] Refugees in Britain Hungarians and Anglo-Egyptians *Planning* 1958, 24 no 419 Published by P E P, 16, Queen Anne's Gate, London S W 1 Pp 35 2s 6d

[2] See *Lancet*, March 29, 1958, p 686

There remains a "hard core" of unsettled refugees from both groups, and, in the case of the Hungarians, this includes a small proportion of adolescent delinquents But in more than this narrow sense the refugee problem, like yesteryear's snow which haunted the poet, is still with us Throughout the world refugees are thought to number little short of 2 million—an estimated 250,000 in Europe, 915,000 Palestine Arabs, 700,000 mainland Chinese in Hong Kong, and 10,000–15,000 Europeans (mostly White Russians) in China and Hong Kong[3] Of these Mr CHRISTOPHER CHATAWAY and his colleagues[4] write

> "We talk of tolerance, justice, and the dignity of mankind, and all over the world we find stagnant pools of humanity, who have been robbed of all these things, who stand behind wire, dragging their uncovered roots, friendless, soilless, waiting for ground in which they may grow again into citizens Their presence mocks loud at our pretentions of civilisation How enlightened can we be when so many plain people are cast out by fear?"

CHATAWAY and his colleagues believe that a World Refugee Year, in which Britain should play a leading part, would go far towards solving this vast problem

Chimeras and Antibodies

INSIGHT into the mechanism of antibody formation can be gained by studying the effects of irradiation Animals subjected to whole-body irradiation with X rays die from hæmorrhage, anæmia, and infections Sometimes the blood-forming tissues are completely destroyed, and erythrocytes, leucocytes, and platelets disappear from the blood (but this can be prevented by shielding the spleen from radiation) When the blood-forming tissues are destroyed the irradiated animal may still survive if a suspension of bone-marrow from a normal animal is injected intravenously The blood-forming tissues apparently return to normal a few days after the injection, and the regenerated bone-marrow and peripheral blood-cells in the treated animal are derived from the donor cells Usually, of course, grafts from other animals do not take, but in these irradiated animals *not only* are the blood-forming tissues destroyed but the immunological mechanisms are damaged, and the irradiated animals accept grafts which would be rejected by normal animals The regenerated tissues being derived from the donor tissues, the way is open to colonisation by further grafts, compatible with the donor, that would be rejected by the recipient animal if it had not been irradiated

The obliteration of the heterologous-graft-destroying mechanism by irradiation raises the possibility of producing chimeras Thus mice receiving a lethal dose of X rays can be saved by the injection of bone-marrow cells from a normal rat, and, in the treated mice, rat granulocytes are found in the blood-forming tissues and rat platelets in the blood But, although these chimeras survive the radiation damage for a month, they may subsequently lose weight, and they have a high mortality-rate Immunological intolerance of the foreign cells develops gradually, in some cases the host animal rejects the donor cells, and at times the foreign donor cells show an immunity response to the tissues of the host The transplanted cells can transfer specific sensitivity to certain tumours from the donor to the irradiated recipient animal The more dissimilar the donor and recipient, the larger the dose of myeloid cells required to save the irradiated animal and the shorter the survival-time, whereas isologous grafts among members of the same closely inbred strain of animals are the most effective

The contribution of the study of irradiated animals to the elucidation of immunological problems is evident from the account of a symposium[1] sponsored by the Oak Ridge Laboratory in Tennessee The symposium dealt primarily with bone-marrow transplantation in irradiated animals, but its scope included recent work on antibodies Although the immunological work is not always directly connected with the main subject of the symposium, it is clearly related and forms a link with results derived from different methods of study It is reported, for example, that turkey erythrocytes appear *in the circulation of chimeras* produced by grafting adult turkey spleen on to the chorioallantois or into the cœlom of chick embryos—an observation immediately reminiscent of work on radiation chimeras The identity of the cells responsible for antibody formation has long been debated, and it was suggested at the symposium that a large pyroninophilic cell, derived from a primitive fixed reticular cell, may be responsible After antibody has been formed as a result of the primary antigenic stimulus, these large cells are transformed into either small lymphocytes or mature plasma cells, which then disappear from the spleen and probably enter the circulation These suggestions may be considered in the light of a hypothesis put forward by SPEIRS,[2] who postulates a two-stage effect The first effect of introducing antigen into the body is migration of granulocytic cells into the area, and there is a specific eosinophil response if the host has been previously exposed to the antigen The antigen induces specific enzyme formation in the eosinophil cells, which are then subjected to phagocytosis by reticulo-endothelial cells These in turn utilise the specific enzymes from the ingested eosinophils to form antibodies While antibody is being formed the reticulo-endothelial cells undergo nuclear changes, becoming increasingly pyroninophilic and being transformed into plasma cells

It is becoming clear that, although antibodies appear to be normal serum-globulins modified so that they react specifically with the appropriate antigen, they *are not* formed by modification of pre-existing globulins *but are* synthesised de novo from the aminoacid pool in the body The complete synthesis of an antibody molecule from the constituent aminoacids takes less than half an hour—an achievement which dwarfs the mightiest efforts of the organic chemist. The chemical mechanism by which antibodies, or indeed any proteins, are synthesised is obscure, but it seems that specific nucleic acids from the cell nucleus play a part in organising the arrangement in proper sequence of aminoacids in the polypeptide chains of the protein molecule. Hypotheses as to how nucleic acids effect this organisation tend to become more complex, and a current suggestion is that the specific antigen modifies deoxyribonucleic acid in the cell nucleus, conferring a heritable change. This modified nuclear deoxyribonucleic acid, it is suggested, transfers appropriate specificity to ribonucleoprotein templates responsible for organising the synthesis of antibodies. These templates, in conjunction with high-energy phosphate bonds in adenosinetriphosphate, are regarded as activating aminoacids so that appropriate ones are brought into juxtaposition and react together to form the specific polypeptide chain of aminoacids. Once antibody formation has been initiated, the amount of antibody present in the body at any time is the resultant of a dynamic equilibrium between the synthesis of new antibody molecules and the degradation of old ones back to aminoacids. Antibodies to the same antigen are not identical and their breakdown-times vary. In the case of Forssman antibodies to sheep red blood-cells in a rabbit, for example, the half-life of the antibodies present varied from 2·8 to 5·6 days.

[1] *J cell comp Physiol* 1957, 50, suppl 1

[2] Speirs, R S *Nature Lond* 1958, 181, 681

Turning to the interaction of antigens and antibodies, in the case of protein antigens it is the carboxylic-acid groups of the antigen that react with amino groups of the antibody molecule. Some indication of the size of the combining sites of antigen and antibody has been obtained in the case of antibodies to dextran. Inhibition studies show that the combining sites are larger than three glucose molecules and approximate to the size of a hexasaccharide. All evidence, however, indicates that antibodies are heterogeneous, and the antibody to any specific antigen cannot be regarded as a precisely constituted chemical compound of reproducible properties. In fact the antibodies present in a single animal at any one time differ widely. As more is learnt about immunology the subject becomes more complex rather than simpler.

Annotations

LEADERS IN RESEARCH

LEADERSHIP in research is a subject of great moment not only to scientists but also to the general community. Few people are better fitted to discuss this subject than Sir Charles Harington. In the first Russell lecture at St. Andrews[1] he had some telling things to say about the career of pure research—pointing out that, although its appeal to the young may be overpowering, there is a risk that in middle age it may prove emotionally unsatisfying, and that a little contamination with teaching or administration may be more satisfactory in the end for many people.

Sir Charles deals with leadership under the headings of Universities, Industry, and Government-supported research. He finds that in the long run leadership is a matter of unselfishness and kindness, in this the *Führerprinzip* has no place. The good leader helps to encourage collaboration between unrelated departments, to see possible fundamental discoveries in routine work, and to guide interest into paths likely to be profitable, and he is always on the alert to spot talent and encourage originality. Thus he aims to foster in the universities new ideas and lively teaching, in industry any work, bearing on the business, which has possibilities of originality, and in Government-supported institutions freedom combined with use of the vast resources which only the State can provide to foster work of value to the public. Sir Charles is as hesitant to direct the leaders as he suggests they should be in directing their own staffs, but he gives them, largely by implication, detailed advice which illuminates the way in which he has learnt to exert the best kind of leadership himself.

He says, quite rightly, that he is talking about leadership, and therefore gives little space to the kind of research that is not susceptible of direction. But it may be thought that he dismisses too easily the kind of research which consists, in his own words, in "seeing correlation between items of knowledge at first apparently quite unrelated". At its best such work (of which one example is Hunter's sudden perception of the relevance of the flushing of the deer's antler, after tying the artery, to the possible treatment of a popliteal aneurysm) requires a mental activity that was described by Livingston Lowes in *The Road to Xanadu* as the essence of genius. Sir Charles Harington maintains that this kind of discovery was characteristic of the early history of Science, and he adduces the sudden leaps forward in the arts, followed by "periods of stunned assimilation", as a parallel. He contrasts this with the continuous growth of Science today, with fact being piled on fact, each advance depending heavily on what has gone before. This analysis ignores the fact that the innovators in the arts were seldom the people who exploited the ideas: fugues were not invented by Bach, symphonies by Beethoven, or leitmotivs by Wagner. The impact of genius on research is as significant today as it ever was: if thought of in terms of discoveries per half-century, it is even more so. What else was Fleming's original observation which led to the discovery of penicillin? Sir Charles rightly stresses that a leader may help his staff to draw the significant conclusion from routine observations and may do much to encourage the power of observation. It is surely useful for the man who can jump to far-reaching conclusions to have a team working with him, who not only exploit the original idea but learn at first hand the significance of the notion that such ideas are possible.

RETROLENTAL FIBROPLASIA

Crome[1] has lately described, under the title "retrolental fibroplasia", 2 cases of bilateral detachment of the retina in infancy. In the first of these, a premature baby had received supplemental oxygen after birth, and besides retinopathy had a patent ductus arteriosus, renal calcinosis, and some evidence of encephalopathy. In the second, a full-term infant who was not subjected at any time to hyperoxia had detachment of the retina together with widespread congenital abnormalities In discussing these and other similar cases, Crome supports the view that retrolental fibroplasia is not always a local intraocular condition, but is only one manifestation of a disease that may involve other tissues, especially the central nervous system

---

[1] Leadership in Scientific Research. Sir David Russell memorial lecture no. 1. By Sir CHARLES HARINGTON. London: Oxford University Press. 1958. Pp. 27. 3s. 6d.

[1] Crome, L. *J. Path. Bact.* 1958, 75, 163.

When Terry[2] introduced the term "retrolental fibroplasia" in *1942*, he intended to differentiate the lesions he was describing from the heterogeneous group of conditions long known under the nebulous but useful title of "pseudoglioma"—a group including all those conditions wherein the white pupillary reflex of retinal glioma was simulated, ranging from developmental abnormalities (such as persistent hyperplastic vitreous) to acquired changes (such as metastatic uveitis) Terry suggested three criteria for the condition he named prematurity, bilateral lesions, and their first appearance after birth Associated somatic or neurological abnormalities were not included It is now common knowledge that the disease for which these criteria were stipulated results from the administration of supplemental oxygen to the premature infant The causal relation of ambient hyperoxia to intraocular changes is very striking and has been abundantly proved, both by the production of analogous changes in laboratory animals[3-5] and by the virtual disappearance of the condition when administration of oxygen is controlled[6, 7] Thus exposure to hyperoxia may now be added to the three original criteria

In 1946, however, Krause[8] reported 18 cases which were similar to those of Terry, but in many of which there was also mental retardation, hydrocephalus, or other cerebral lesions, and Krause therefore proposed the term "encephalo-ophthalmic dysplasia" Rereading his paper with the knowledge we possess today, we find that Krause was applying the name to cases of different types, in 5 the eye changes were clearly congenital *Examples of so-called retrolental fibroplasia have been* described in which either oxygen was not given[9-11] or the infants were full-term[12, 13] But close examination of these reports shows that the name is being applied descriptively to conditions ætiologically dissimilar—the later stages of oxygen-induced retinopathy are in no way specific and may result from a wide variety of causes Similar intraocular damage has been observed not only in the other pseudogliomas but also in hereditary diseases such as incontinentia pigmentosa,[14] and it has been induced experimentally both by anoxia[15] and by vitamin deficiency[16]

Ending this confusion will depend largely on whether oxygen-induced retinopathy of prematurity may be accepted as a distinct entity not essentially associated with extraocular abnormalities Unfortunately it is impossible to be certain that the effects of oxygen exposure are confined to the eye, because there is a lack of data on the incidence of general somatic abnormalities in cases with and without retinopathy, *there is no agreement* on the significance of associated mental retardation,[17, 18] and, the disease not being lethal, necropsy reports are few Nevertheless, it seems that there is no obvious pattern of general somatic or neurological abnormalities consistently associated with oxygen-induced *retinopathy*, most cases are entirely free from extraocular abnormalities, and there is good evidence that *in laboratory* animals the damaging effects of long-continued hyperoxia are confined to the retina[19, 20] Hence there are no sure grounds for believing that any neural or somatic abnormalities are ætiologically related to concomitant oxygen-induced retinopathy

What then are we to call the type of case reported by Crome? It would probably be better now to abandon the name retrolental fibroplasia (which in any case is not particularly appropriate) and to replace it by "oxygen-induced retinopathy of prematurity", an extension of the name first proposed by Heath,[21] and to reserve this strictly for cases where the retinopathy develops after birth in premature babies subjected to hyperoxia The old term "pseudoglioma" may be retained for cases where the cause is uncertain or unknown Thus Crome's first case would be termed "oxygen-induced retinopathy of prematurity with associated abnormalities" and his second case "pseudoglioma with associated abnormalities"

PROGNOSIS IN RHEUMATOID ARTHRITIS

In trying to decide whether to use or to withhold a potentially dangerous drug in a case of rheumatoid arthritis the clinician must consider not only the risk and the possible benefits of treatment but also the seriousness of the disease in his patient Accurate information about *the benefits of treatment* can be gleaned only by the laborious method of controlled clinical trial Information about prognosis is no less difficult to obtain, involving as it does protracted study of a large enough group of patients to contain examples of the many types of course which the disease may follow Such studies have yielded fairly consistent figures for the amount of disability to be expected in each such group after various periods of time They have also made it possible to predict, though not as yet very accurately, the probable course in any individual patient

The rheumatic unit in Edinburgh has kept under close observation a group of patients with rheumatoid arthritis admitted to hospital between 1948 and 1951 Most of these patients have been watched for six years, and the changes in their condition have been described by Duthie and his colleagues[22] On admission to hospital 22% of the patients were unable to work or to look after themselves without help Incapacity of this degree must have arisen mainly from active inflammation in the joints rather than from advanced irreversible deformity and damage, for at the time of discharge from hospital only 0 4% remained in this lowest category of functional capacity This group of severely disabled patients is bound to be enlarged, as the years pass, by the added restrictions of old age and by fresh onslaughts of active-disease, that it should still account for no more than 9% of the whole series six years after discharge is gratifying Although the criteria used in similar investigations elsewhere have varied, this figure is close to the 10% found by Ragan[23] as the proportion of patients confined to bed or chair after five years of observation At the opposite end of the scale are the patients—11 3% of the total—who were fit for all normal activities when they left hospital After two years, in which some patients with moderate disability improved, the figure had risen to 28% During the next four years this group diminished only slightly This is again in keeping with experience in the U S A —in New York Ragan found no remaining evidence of arthritis in 26% of his cases (with another 22% suffering no more than occasional joint pains), and in a carefully analysed series from the Massachusetts General Hospital Short et al[24] found 13% of their patients in remission after an average of fourteen years of observation

In the Edinburgh study treatment consisted in a "basic regimen" in hospital of rest in bed, the application of plaster splints to affected joints, the largest tolerable doses of aspirin, physiotherapy, and a graduated return to the highest attainable functional level The Boston patients were kept in hospital for a shorter time than those in Edinburgh, otherwise the programmes of treatment did not materially differ The two groups of investigators agree that patients admitted to hospital early in the course of their disease fare better than those admitted later, in Boston 37% of those admitted in the first year of their disease were in remission after observation extending in the majority to at least five years from discharge, only 4 7% of patients admitted later in the course of their disease did as well as this In Edinburgh 43% of patients admitted in the first year but only 10% of those admitted between the fifth and tenth year were free from any restriction in activity six years after discharge

The time of admission to hospital largely reflects the pattern of the disease thus cases admitted soon after onset will in general be those in which the disease has progressed rapidly, and in which disability arises mainly from inflammation in the joints rather than from irreversible anatomical damage In cases admitted later the disease clearly has either failed to abate after several years of continuous or intermittent activity, or has produced permanent damage It is not surprising that these two broad groups should differ in prognosis The Edinburgh report draws attention to two groups not included in its material—milder cases in which treatment in hospital is not thought necessary, and cases in which the patient never seeks medical help The second of these categories has been estimated[25] to account for 38% of women and 19% of men with rheumatoid arthritis

As regards other considerations helpful in prognosis the Edinburgh and Boston groups agree that men do rather better than women, and that an acute onset and a rapidly progressive course in the early months is favourable, a good response to treatment in hospital also augurs well for the future Finally it is becoming clear that the presence or absence in serum from cases of rheumatoid arthritis of the factor which agglutinates sensitised sheep erythrocytes has an important bearing on prognosis, in that patients with a negative agglutination test do well Duthie and his colleagues found a direct relationship between functional capacity and the concentration of the agglutinating factor

Although patients admitted to hospital early in their disease are a selected group, and probably likely to fare better than average however treated, few clinicians would seriously doubt the value of a period of treatment in hospital Like most of the other elements in the "basic regimen", treatment in hospital has not been, and should not be, submitted to controlled trial The patients whose course has been so closely studied in Edinburgh were treated by these sound and uncontroversial methods in a unit largely concerned with the problem of rheumatoid arthritis While there are no comparable figures for patients who have had less comprehensive care, there can be little doubt that the programme of continuous treatment and supervision, supplemented by skilled assistance in the solution of domestic and employment difficulties, contributed to the maintenance of independence and the ability to earn a living in so high a proportion of patients It is against results of this sort that any alternative or supplementary method of treatment must be measured

OLD PEOPLE AND THEIR FAMILIES

AN important investigation into the relations between old people and their families is described by Mr Peter Townsend,[1] who has based his observations on old people selected at random in Bethnal Green He visited over two hundred families, and it speaks volumes for his tact and patience that his searching questions were readily answered Several notable facts stand out Comparatively few old people were seriously isolated Many who lived alone had relatives nearby but preferred to maintain a "supported independence", seeing their families every day but not sharing a roof with them Their family interests embraced three generations, and each old person had on an average thirteen members of such an extended family living within a mile and kept in touch with most of them The elderly women were by no means passengers, and although they had much help from female relatives they made their own contribution when they could by providing midday meals, by caring for grandchildren, and in other ways This contribution by the grandmother gives her a permanent and valued role in the family and contrasts with the tragic uselessness that retirement brings to many men, when their income falls and they are excluded from their former social activities and cut off from their friends

About one in five of the old people had no children to support them Not all of these "isolates" complained of feeling lonely, a sense of loneliness affected principally those who had recently been bereaved or separated from their families, a group which Townsend calls "the desolates" But those without children were making the biggest demand on the social services At a local geriatric hospital the proportion of childless and unmarried among the patients was 43%, compared with 18% among the elderly population of Bethnal Green as a whole, and figures were similar among the occupants of a local welfare hostel and those in receipt of home help Townsend produces convincing figures to show that, as the variations of family circumstances are followed through to those with sons and daughters-in-law but no daughters, to the childless, and finally to the unmarried, the availability of family help diminishes and the claims on the social services increase This is particularly noticeable in single or widowed men who once they become infirm are much less independent than old women Various estimates suggest that but for the help given by female relatives the number of old people seeking admission to geriatric hospitals and welfare homes might be three to five times greater than it now is

[1] Townsend, P The Family Life of Old People. London Routledge & Kegan Paul 1957 Pp 284 30s

About two-fifths of Townsend's subjects were infirm or living with an infirm spouse, and one in three had been in hospital within the past five years (A similar proportion of "infirmity", defined as confinement to a house or restriction of outdoor activity, was found in Sheffield [2] and in a London suburb [3]) One in eight had caused a relative to give up paid work in order to look after them, and at least to this extent were imposing a strain upon their families

What can be done to support the family in its task? Townsend suggests a comprehensive family help service, to experiment with alternatives to institutional care—boarding out the isolated, transforming old houses into self-contained one-room flats with housekeepers in charge, and finding accommodation for relatives This service would also extend the existing home-help arrangements to relieve overburdened relatives in the evenings and for holidays Already the home-help service is of the greatest value and could profitably be expanded [4], and, as Chalke [5] has observed, its worth cannot be measured merely in terms of hours of work In a few places night attendants enable the relatives of old people who are restless at night to get an occasional unbroken night's sleep Sometimes an infirm person cannot stay at home because a daughter cannot afford to give up her job to look after him A constant-attendance allowance, such as is already paid to some war pensioners, might make all the difference, and Mr Townsend proposes, as he explains in his letter on p 910, that this allowance be extended to include bedridden old-age pensioners

The strain on the family can also be eased by anything which contributes to the old person's physical and mental independence Fry [3] suggests that it is the duty of the family doctor to get to know all the old people on his list and to keep in touch with them On a larger scale, the welfare department of the city of Salford is to be commended for making its services known by giving every person reaching pensionable age a booklet which contains a reply-paid postcard for those who desire a visit The health visitor, at once a nurse and a social worker, can, by regular visits, do much to prevent that gradual deterioration in old people which goes on slowly until, in Townsend's words, "a neighbour sees a bottle of milk standing on the doorstep long after it has been delivered, makes inquiries and sends for an ambulance" Old people's clubs and unofficial friendly visiting by volunteers also preserve an interest in life and the self-respect that goes with it "Meals on wheels", a voluntary service which is well established in many towns, gives a useful boost to morale, and in a few places help with laundry has been arranged Chiropody also is important in keeping the elderly fit Finally, domiciliary physiotherapy may have a useful future, as has been shown in Belfast [6]

Townsend is right to suggest that these many services should be "closely connected with the work of family doctors" Walsh [7] has discussed the value of these services in general practice, and Fry proposes that the medical officer of health should be available for domiciliary visits as "a consultant in social medicine" Others, including apparently the Minister of Health,[8] see here one of the special functions of the geriatrician, and a good geriatric outpatient department with an almoner, physiotherapist, and occupational therapist working together, when necessary within the framework of a day hospital, will undoubtedly achieve more and more in the future

TIETZE'S DISEASE

In 1921 Tietze [9] described four cases of "swelling of costal cartilages of unknown ætiology, insidious in onset, spontaneously painful, not associated with constitutional disturbances, and of a prolonged, fluctuating course" He believed that this might be a cartilage dystrophy, possibly associated with wartime malnutrition In Britain the disorder was first noted in 1942 by Gill et al,[10] who described five cases in young soldiers and considered that symptoms and signs might be present for a very long time Histological examination of costal cartilage in one of their cases showed no departure from normal Deane [11] found that the second costal cartilage was most commonly affected, and he noted that a painful swelling at onset might be associated with a respiratory infection, the pain diminished but the swelling often remained The histological changes in biopsy specimens of costal cartilage they regarded as variants of normal They suggested that the disorder originated either in a small tear or in rheumatoid involvement of a ligament Beck and Berkheiser [12] described four cases in which the costal cartilage was exposed at operation and was found to be acutely buckled forward They suggested that this buckling was due to disease of the underlying ligament, but no specimen of ligament was taken for examination The difficulties in the differential diagnosis of this condition have been indicated by Wehrmacher [13], but there is no doubt that familiarity with the syndrome makes its recognition fairly simple

Karon et al [14] have now described thirteen new cases Their criteria of diagnosis are (1) the presence of a painful, tender mass in one or more costal cartilages, (2) evidence that the mass is a distinct enlargement, not present normally, which eventually subsides, and (3) the absence of a definite alternative ætiological diagnosis The swelling and tenderness usually make the diagnosis immediately apparent, and radiography and hæmatological investigations eliminate underlying disease of rib, lung, or heart There is no specific treatment, and in most cases reassurance and local heat and analgesics suffice Surgical excision should be unnecessary, provided the diagnosis is not in doubt Local infiltration of hydrocortisone in patients who do not respond immediately to simple measures may be expected to bring prompt relief from pain together with diminution of the swelling [15]

Prince Philip, Duke of Edinburgh, has accepted the invitation of the British Medical Association and the Canadian Medical Association to be their president for 1959–60 The associations are holding their annual meetings jointly in Edinburgh in July, 1959

Symposia

TRAINING

The Betterment of Human Effort

A SYMPOSIUM arranged by the Ergonomics Research Society in Bristol on April 13–16 tackled the Problems of Training, and the discussion ranged as widely as the title suggested it would As Mr M G BENNETT, of the operational research division of British Railways, remarked, ergonomics is a funny subject for one thing, its scope is certainly very broad indeed One of the difficulties which face those engaged in the study of man in relation to his work—industrialists, psychologists, doctors of several sorts—is that there are huge practical tasks to be completed in industry and elsewhere at a time when relatively little is known about the theory of the subject. And with so many different people involved, meetings of the kind which the Ergonomics Research Society arranges are an enormous help Last week's meeting was well attended, but perhaps some groups vitally concerned were not as fully represented as they should have been At the close of the symposium, Prof R C BROWNE (Newcastle upon Tyne) said he would like to see at next year's meeting more young executives from industrial organisations, more lecturers from university departments of engineering and colleges of technology, and more young doctors from industry

The account that follows includes only some of the papers read at the symposium and we have given particular attention to the contributions with a medical content. This unbalanced picture does not therefore record many important matters concerning training for skilled employment, which occupied much of the symposium's time

TRAINING AND THE HEART

Dr M J KARVONEN (Helsinki) discussed the effects of physical training on circulatory dynamics The "trained" cardiovascular system might be said to be one in which a high cardiac output was associated with a high oxygen uptake The heart-volume was usually increased and the resting pulse-rate was often but not always slow The diffusion capacity of the lungs was closely related to the condition of training of the cardiovascular system, and diffusion capacity at rest showed a negative correlation with pulse-rate during standard exercise and with age Several pulse-rate tests had been used to assess the degree of training, and the step-test pulse-rate had been found to be closely correlated to the resting rate, the maximum rate, and the increase in rate between rest and work The heart-volume of a group of long-distance runners was round about 600 ml per sq m of body surface, for sprinters the figure was between 300 and 400 ml per sq m During a hard training season the size of an athlete's heart could increase considerably To produce a drop in the pulse-rate during standard exercise, training exercises must raise the pulse-rate above 130–140 per min Below this level, Dr Karvonen had found no training effect on the cardiovascular system, and he concluded from pulse-rates commonly observed during occupational work that such work had little training effect on heart function. The gentle trot to the station seems, therefore, of little value from this point of view it is better to leave three minutes later and go in for a full-blooded sprint

Training, it was said, made man better adapted to exercise, but, Dr Karvonen added with a twinkle, it might also be argued that lack of training made man better adapted to rest In fact the work done by the trained heart at rest was half to two-thirds less than that performed by the untrained heart The higher maximum cardiac output conferred a greater capacity for work and under certain conditions (e g, in heat and while flying under accelerating forces) this was a particular advantage

Some people said that training of the cardiovascular system was dangerous, but Dr Karvonen had no such fears At a few critical moments, a trained cardiovascular system was a distinct help Women with small hearts were more likely, it seemed, to give birth prematurely than heartier mothers, and a study of champion skiers' prospects of reaching old age showed that their insurance companies had little to worry about Dr Karvonen concluded modestly that the evidence indicated that exercise was "not acutely toxic to the organs"

TRAINING AND THE LUNGS

Dr J E COTES (Cardiff) described some investigations he had carried out with a colleague, Mr F Meade, into the effect of training on pulmonary ventilation during exercise 11 young men were studied before and three times during their National Service preliminary training course Ventilation, end tidal pCO_2, and body-temperature were measured at rest and while walking at $3^1/_2$ m p h on a motor-driven treadmill. The rate of working against gravity during the treadmill walk was calculated from the vertical oscillation of the body During the weeks of their training, the men's ventilation minute volume, total energy expenditure, and vertical work done all decreased The reduction in energy expenditure could be fully accounted for by the reduction in lift work A graph of the rate of energy expenditure against rate of lift work gave a straight line—the line of constant efficiency of conversion of chemical to mechanical energy The findings suggested that the greater part of the reduction in pulmonary ventilation with training was due to increased economy of performance There was also evidence of increased arterial oxygen tension as the result of training No change was noted during training in the ventilation equivalent for oxygen, perhaps because the work level was well below that necessary to induce anærobic metabolism Dr Cotes suggested that the men used less air in the performance of a standard task by virtue of greater economy of effort and more efficient aeration in the lungs, with a consequent increase in arterial oxygen tension

PHYSIOLOGICAL BASES OF TRAINING

Prof A HEMINGWAY (Leeds) spoke of the two main types of training the imposed disciplining of patterns of movement and the development of resources so that tasks previously impossible came within the individual's capacity If a worker was trained according to physiological postulates concerning movement and posture then he could work more economically Improvement with training came as the result of better coordination of muscles and the elimination of unnecessary movements The extension and improvement of the physiological capabilities of the individual enabled him to perform a given task with less encroachment on his reserves or with greater efficiency In artistic activities or sport, however, excellence of performance, as judged by skill, endurance, or strength, counted for more than efficiency, and training was then directed at exploiting the potentialities of the body and at the development of fitness for a task, "the growth of the wisdom of the body"

Professor Hemingway mentioned Dr Roger Bannister's views on the importance of a certain mental approach in the athlete that enabled him to endure when physical discomfort was intense, and he also illustrated some training schedules of the repetition type, involving alternate fast running and recovery phases, that many trainers now believed to be the best way of bringing a middle- or long-distance runner to peak performance

EIGHTEEN MILES A DAY

The effect of short periods of exercise, lasting a few days, on the fitness of relatively untrained young men has not been closely studied, and Dr J V G A **Durnin** (Glasgow) decided to look into the matter 44 young men in an R A F unit, who had had almost no exercise, were divided in four groups one group continued to take almost no exercise, the second walked 6 miles a day, the third 12 miles, and the fourth 18 miles over hilly country on rough tracks and metalled roads Cardiorespiratory function was measured during a standard exercise on the treadmill and these measurements were made before the beginning of training, at the end of five days' exercise, and at the end of ten days In all the marching groups, there was a significant decrease over the training period in the exercise heart-rate compared with the controls, and the 12-milers also showed a significant decrease in pulmonary ventilation and oxygen consumption In no group was the change in heart-rate 1–1½ minutes after exercise significant Perhaps the most surprising of Dr Durnin's observations was the casualty-rate from sore feet—only 2 men incapacitated for half a day each

During discussion it was asked what a high mark in the Harvard step test indicated, and one answer was "fitness to do the Harvard step test" But Dr O G **Edholm** (London) had more confidence in it as a measure of physical fitness, even though it was not ideal *

HARD WORK

Mr J G **Fletcher** (London) had found that "well-motivated" young men could increase their maximal amount of physical work very rapidly by exercising once a day to exhaustion, using a constant high rate of work The physiological changes were investigated and the rates of improvement compared in different subjects A simple work test (stepping up and down on a 22-inch bench thirty times a minute for as long as possible) was used, so that the acquisition of skill played no great part in any improvement The reactions of 10 healthy men between 20 and 46 were studied At first men in poor shape could continue stepping for only about a minute, but a cross-country runner was able to carry on for 35 minutes Endurance improved rapidly with repetition, and 3 non-athletes achieved 15 minutes An ex-athlete and swimmer got up to 30 minutes from a poor start in only 8 attempts, an Antarctic explorer took about twice as many attempts to get up to 15 minutes, and a sedentary worker reached 15 minutes only after about 30 attempts The resting heart-rate was lower after training than before it, and recovery rate after work was more rapid Those people who were retested after an interval without training all retained some improvement Mr Fletcher concluded that in this type of exercise maximal output could be much increased provided (and there was the rub) "subjects are prepared to work to exhaustion"

INCREASING MUSCULAR STRENGTH

Prof E A **Muller** (Dortmund) looked on a muscular contraction as having two different effects—one preventing atrophy and the other increasing strength Atrophy, he had found, was prevented by one short static contraction daily of at least 20% of the maximal strength At least one short static contraction a week of 35% maximal strength was needed to ensure increase in the strength of a muscle Muscular strength could be increased much more rapidly by daily contractions, but the benefit was lost correspondingly quickly after "training" was stopped Professor Muller and his colleagues at the Max-Planck-Institut fur Arbeitsphysiologie had found, however, that there was nothing to be gained by increasing the training stimulus by stepping up the daily number, duration, or force of the contractions Strength reached by quick training could be kept undiminished by one contraction a fortnight, and maintained in that way for several weeks, it would then persist without further training

NOISE AND TRAINING

Mr D E **Broadbent** (Cambridge) had been investigating the effects of noise early in training upon subsequent performance The design of previous experiments had divided the subjects in such a way that half learned a task in quiet conditions and half in noise The environments were then reversed and the effect on performance noted In general it was found that those who had learned the task in quiet performed better during the second session—in other words, and not unexpectedly, the conditions under which a man first met a task affected his subsequent performance when conditions improved In several experiments it was noted that the subjects learning in noise did badly throughout the experiment, including their subsequent performance in quiet These experiments were not entirely satisfactory in that there were only two groups (noise→quiet, and quiet→noise), so that the findings could have been accounted for if a practised task was done better in noise than in quiet Mr Broadbent, therefore, added a third group (quiet→quiet) and repeated the experiment The subjects memorised a six-figure number shown to them the number was concealed, a four-figure number displayed, and the subjects had to subtract one from the other in their heads The time they took for each problem was taken as the measure of efficiency At the first session of tests the two groups in quiet improved their times, but the group in noise got worse At the second session, after the first two groups had reversed their environments, the noise→quiet group again deteriorated considerably, while the quiet→noise subjects maintained their efficiency (as judged by time per problem) almost unimpaired, and the quiet→quiet competitors went on improving happily These findings emphasised the importance of paying as much attention to the environment of workers in training as to that of workers in the production line

PRACTICE MAKES IMPERFECT?

Dr O **Graf** (Dortmund) reported some more interesting work at the Max-Planck-Institut In two experiments with 4 female workers spaced practice (4 fifteen-minute spells daily) at an operation for punching holes in cards was compared with continuous practice (eight hours daily) The striking finding was that spaced practice over a period of fourteen days produced surer movements and faster work than continuous practice spread over four months Other types of work studied in this way were bradawling and riveting The influence of fatigue in continuous practice might, Dr Graf suggested, lead to the development and retention of incorrect movements which slowed down the operation

* In a letter on p 912 a correspondent refers to variations in the technique of performing this test —Ed L

SKILL AND NATURAL SELECTION

Imagine a learner, suggested Dr E R F W **CROSSMAN** (Reading), with a repertoire of different methods for doing the job he is learning, each method with its own probability (strength) and time If the methods taking longer were negatively selected, many methods would increase in strength Laboratory and industrial observations with element-by-element recording apparatus had shown that the speed of an operation increased through a change in the shape of the frequency-distribution of element-times rather than from a bodily shift in its position These and other findings suggested that skill was acquired by the unconscious selection of appropriate methods from an initially random assortment Selection must depend on something more than conscious knowledge of results—perhaps on unconscious perception of the time taken by each element More likely, however, Dr Crossman thought, was the unconscious selection by the operator of those methods which required least work on his part, so that increased speed was secondary to reduced effort

CASES AND PAVING-STONES

Dr F H **BONJER** (Leyden) had measured energy expenditure, pulse-rate, working time, and amount of work performed during certain jobs Various methods of handling cases while stowing them in the hold of a ship had given the following results

	Tilting on long edges	*Tilting on short edges*	*Tilting on edges with hook*	*Tilting on angular points*
Energy expended (kg-cal. per case)	2 2	2 5	2 2	1 2
Heart-beats per case	135	136	152	123
Work done (kg-m per case)	111 3	107 6	107 6	71·4

The best method, judged by these figures, was to manhandle the case on its points, and Dr Bonjer showed diagrams to illustrate that workers using his method were able to keep a more upright posture than those using other methods

Dutch paving-stone layers are divided into three schools—standers, sitters, and kneelers—and Dr Bonjer produced a film to show how each school worked The sitters had a little one-legged stool, which looked uncomfortable, and the kneelers seemed none too happy either, on appearances the standers certainly had it But both standers and sitters, it was found, were laying about 20 stones a minute for the same rate of energy expenditure, and kneelers in the Hague could do just as well, though elsewhere kneelers' rate of laying was not so good But the kneelers had the champion on their side, a remarkable performer who came from a well-known family of pavers and who put down 30 stones a minute These investigations demonstrated the complexities that individual variations could introduce into a group study

PROCRUSTES AND THE WORKING MAN

Procrustes was a fabulous robber of Attica who made his victims conform to the length of his bed by stretching or mutilation, and Dr F V **TAYLOR**, of the U S Naval Research Laboratory, Washington, introduced what he called a " cacophonous note " with a sprightly attack on the " procrustean approach to the optimisation of man-machine systems " Is it better to adjust the human component to the requirements of the system (as Procrustes did) or to enhance system performance by adjusting the mechanical elements to fit the man? Dr Taylor announced unashamedly that he proposed to arrange his data (which could be made to support either approach) so that Procrustes would lose And lose he apparently did For example, in an experiment with operators learning to use two tracking systems (one with a simply learned position control and the other with a harder-to-master acceleration control), training could make the operators of the acceleration control as efficient as those using the simpler device, but they reverted to their original order of merit when the operators were subjected to any one of a wide variety of " task-induced stress situations " Stress disrupted most readily the system which put most dependence on the man, and the procrustean approach might therefore obscure important operational deficiencies of a man-machine system

VENEREAL DISEASES

A W H O seminar on venereal diseases was held in Tokyo on March 17–29, under the presidency of Dr M **YAMAGUCHI** Information was exchanged about venereal disease in the Western Pacific region of W H O

It is evident that in many countries syphilis has declined since 1945 No evidence of widespread endemic non-venereal syphilis was forthcoming, though cases were reported from French Polynesia Yaws is, however, a problem in Laos, Malaya, the Philippines, and the Pacific Islands In general syphilis is being well controlled with penicillin

Gonorrhœa, on the other hand, after a post-war fall is again increasing in many areas, and is not responding to repository penicillin as well as previously Failure-rates of up to 30% are being noted on higher doses than those giving 95% success only a few years ago The gonococcus seems to be becoming less sensitive to penicillin Whether this is because the organism has developed new metabolic processes or, as seems more likely, because of repeated selection of less sensitive strains is not definitely known The need seems to be to provide higher peaks of blood-penicillin by means of shorter-acting penicillin Such preparations lack one advantage of repository penicillins—the long period of penicillinæmia during which the consorts can be secured for treatment before the patient becomes reinfected Mixed preparations containing both short- and long-acting penicillins may provide the answer, but the situation is disquieting

Non-gonococcal urethritis is emerging as diagnostic facilities for gonorrhœa improve It is commoner than gonorrhœa in some Japanese clinics Of the other venereal diseases, chancroid is thought to be the most important, especially where provision for dark-field examination is inadequate In some countries chancroid is several times commoner than primary syphilis, and, if no dark-field examinations are made, cases of chancroid with positive serological tests (due to late latent syphilis or to past yaws) will be unfairly classified as penicillin failures when—as is likely—the tests fail to reverse

It was agreed that there is much more venereal disease in the area than has been reported in the official returns Special one-day surveys in Japan have indicated that 6–10 times the number of cases actually reported may be present

PENICILLIN REACTIONS

Fatalities from penicillin reactions have caused alarm in some countries—notably Taiwan, where some 17 deaths have been reported All countries have experienced deaths from penicillin anaphylaxis which, because patients die in the doctor's consulting-room rather than in hospital, attract attention and publicity Penicillin anaphylaxis is commoner after intravenous than after intramuscular injections, and after any injection than after oral administration. Reactions are thus commoner with the more quickly absorbed preparations, which are those most used in general practice They are much less common in venereal-disease clinics, where repository penicillins are used In a recent W H O survey of over 600,000 patients, there was only 1 death from penicillin in 70,000 treated, and in the W H O -assisted venereal-disease-control programme in Taiwan there was only 1 death in 44,000 treated

Many of the severe reactions have arisen in persons with a previous history of allergy, especially to penicillin It was suggested that many fatalities can be avoided if a careful preliminary history is taken Important in the prevention of such reactions is the restriction of the use of the drug to only well-established indications and of its sale to the production of a doctor's prescription (antibiotics may be bought over the counter in many countries of the Western Pacific region) Some deaths can be prevented by resuscitating drugs, and all doctors who administer penicillin should have on hand an emergency kit containing appropriate syringes, adrenaline, nikethamide, hydrocortisone, an anti-histamine drug for injection, aminophylline, and, if available, penicillinase

LIVER DISEASES

A SYMPOSIUM on liver diseases was held in Lund and Malmo, Sweden, on March 28 and 29, under the joint presidency of Prof J P SANDBLOM and Prof J WALDENSTROM

Dr H VETTER (Austria) described the use of radioactive colloid materials in the estimation of liver blood-flow This is based on the assumption that these substances are removed from the circulating blood by the cells of the reticulo-endothelial system, which are mostly found in the liver This removal is estimated by simply placing a counter between the thighs Suitable radioactive substances are colloidal radiogold and heat-denatured human serum-albumin labelled with ^{131}I In cirrhosis of the liver, comparison of results obtained with colloidal radiogold with those for bromsulphalein showed that two-thirds of the diminished bromsulphalein removal was due to decreased liver blood-flow and not to impaired liver-cell function There was a significant negative correlation between the liver blood-flow and the portal venous pressure

Galactose is metabolised solely by the liver, and Dr N TYGSTRUP and Dr K WINKLER (Denmark) had given this compound intravenously and measured its removal from the blood Liver blood-flow was then calculated Quite small amounts of alcohol diminished galactose removal The mechanisms of this interference were obscure

Dr R L BLOMSTRAND (Sweden) had cannulated the thoracic duct and studied the lymph biochemically 10–50% of the thoracic-duct flow comes from the liver The normal flow was 40–120 ml an hour A patient with cirrhosis produced 500 ml an hour This overproduction would support the hypothesis that ascites is produced from liver lymph Erythrocytes injected into the ascites could be recovered from thoracic-duct lymph

Dr C E EKMAN and Professor SANDBLOM reported their results for portocaval anastomosis in cirrhotic patients with portal hypertension 11 of 69 patients died after operation Preoperative tests showed that 9 of those dying had poor liver function and 2 good liver function This emphasised the importance of reserving this operation for those with good hepatic reserve 42 of 55 survived one year and only 2 had further gastrointestinal hæmorrhage

Dr H KROOK (Sweden) had used the occluded (wedged) hepatic vein technique to measure the portal venous pressure A raised pressure was diagnostic of cirrhosis The presence of vascular spiders correlated with the height of the portal venous pressure

Dr D N S KERR (Britain) described 4 children with portal hypertension due to congenital fibrosis of the liver, a variant of polycystic liver Biochemical tests were virtually normal, apart from a raised serum-alkaline-phosphatase Microscopic examination of the liver showed a normal zonal pattern, the liver lobules being surrounded by dense fibrous tissue containing bizarre bileducts and very few portal veins

Dr M SCHWARTZ (Denmark) had used ^{131}I-labelled human albumin to measure the rate of serum-albumin degradation In normal people and in such conditions as nephrosis, albumin production seemed to follow the serum-albumin level, more being produced when serum levels were low In cirrhosis, however, the rate of metabolism was much less than expected, reflecting the diminished capacity of the diseased liver to synthesise albumin

Dr F SERIN (Sweden) reported a patient with mushroom (*Amanita virosa*) poisoning A period of hepatic failure followed the initial diarrhœa and vomiting, and this was marked by jaundice and a rise in the serum-enzymes aldolase, glutamic oxaloacetic and glutamic pyruvic transaminase, and malic and lactic dehydrogenase These were presumably released by the damaged liver Disturbances in blood coagulation were shown by a fall in Christmas factor and factor V, antihæmophilic globulin was unaffected, and was probably not of hepatic origin

Professor WALDENSTRÖM commented on the group of adolescent patients, with cirrhosis, acne, and high erythrocyte-sedimentation rates, that he originally described in 1950 Jaundice might not be present, and such a patient with predominant portal hypertension had benefited by portocaval anastomosis Dr S SHERLOCK (Britain) had noted that these patients often showed an excessive adolescent growth spurt Dr G H JEFFRIES (Britain) had seen steatorrhœa, which did not seem to be of pancreatic or intestinal origin, and might be due to diminished hepatic production of bile salts

Dr J H ARFWEDSON (Sweden) had studied 100 patients with pruritus in pregnancy He had found disturbed hepatic function in 87, especially in those with severe symptoms A slightly raised serum-bilirubin level and decreased serum-α-lipoproteins were the commonest abnormalities Differentiation must be made between gallstones, virus hepatitis, and the obscure intrahepatic obstructive jaundice of pregnancy described by Dr L THORLING (Sweden)

QUANTITATIVE METHODS IN HUMAN PHARMACOLOGY

A SYMPOSIUM on Quantitative Methods in Human Pharmacology and Therapeutics, arranged by the Coordinating Committee for Symposia on Drugs and supported by the British Pharmacological Society, the Physiological Society, the Royal Society of Medicine, and the Biometric and Nutrition Societies, was held in London on March 24 and 25

Sir CHARLES HARINGTON remarked that it had been said that the invasion of biology by mathematics had robbed it of much of its charm But the quantitative aspects of biology were vitally important, and those who, like himself, hankered after the days when workers could be content with qualitative observations had to recognise that this feeling was a weakness to be sternly suppressed

Quantitative studies gave new information at laboratory and clinical levels They were vital for effective therapeutics

Prof J H Gaddum pointed out that the advance of the science of therapeutics was due not only to the provision of new drugs but also to the methods of measuring their effects—which was, for the first time, to be the theme of a symposium Although there was no effective remedy for the common cold we had at least learnt how to prove that certain remedies were less effective than some people supposed He hoped that nobody would stay away from the session on statistics because they might think it likely to be too difficult He said (to the evident relief of many present) that there was no need for doctors to understand statistics but it was important for them to know what statistics could and could not do for them

OBJECTIVE ASSESSMENT

Dr Harry Gold described problems of measurement in his experience of assessing in patients the effects of xanthine derivatives and khellin on angina pectoris, and of digitalis It was essential, when subjective judgments were being made, that not only the patient but also the doctor should be kept in ignorance of the treatment used Doctors, he said, had little difficulty in accepting the power of suggestion as applied to their patients, but the notion that the same applied to the doctor had not had an equally cordial reception Experimental therapeutics had come to depend on the development of accurate pharmacological techniques in man, there was no escape from it Resistance to the idea that exact measurements were needed still existed, however, it was due to faulty thinking

METHODS OF EVALUATION

Prof C A Keele described the measurement of analgesia in man He declined to define " pain ", remarking that it was an experience we could all recognise easily enough Measurement of pain indirectly by means of the observable concomitants (sweating, wincing, changes in heart-rate, &c) had not been as satisfactory as simple subjective assessment He proposed an index obtained by multiplying the pain-relief score by the side-effects score, calling this the " score of contentment ", which would enable the therapeutic usefulness of drugs to be compared conveniently

Dr Peter Sainsbury discussed the measurement of bodily changes accompanying emotion Measurement of muscle tone and involuntary movements was practicable with minimal disturbance of the patient, and it could be reasonably quantitative He was able to measure the amount of gesture, fidgeting, and tie-adjusting, as well as muscle-tone, and to record the effects of drugs on these

Dr H Steinberg described the measurement of the effects of drugs on various kinds of performance—reasoning, association and memory, perception and vigilance, and motor coordination and speed Complex intellectual performance had been little studied quantitatively, probably because of the difficulties, but interesting results were being obtained It had been shown, for example, that drugs might reduce performance in a test by reducing incentive and not by interfering with ability to perform During intellectual tests knowledge of results could act as a spur, and the effects of some drugs had been shown to differ according to whether or not this spur was present Small amounts of anxiety acted, as expected, as an incentive to performance, but large amounts were incapacitating The effects of drugs on these factors could now be measured

Prof L Goldberg described how it is possible to measure the effects of drugs on motor activity and stability He instanced an experiment in which Romberg's test was performed with a light attached to the subject, the movement of which was recorded on a photographic plate

Dr H K Beecher discussed the measurement of subjective states He suggested that pharmacologists did not play a large enough part in experimental therapeutics, remaining detached from the clinic, which was too far beneath their ivory towers for them to notice it He thought (and the meeting obviously agreed) that the accurate measurement of subjective states was one of the most important advances in experimental therapeutics

STATISTICAL METHODS

Dr W G Cochran lucidly described the use of such techniques as Latin squares, randomised blocks, and sequential analysis, and their merits in assessing responses to drugs Dr C C Spicer discussed the statistical treatment of results when these could only be assessed semiquantitatively by grading into pluses and minuses by the observer Such a method could be accurate and reproducible Dr D J Finney asked whether the habit of expressing doses of drug as weight per kilogramme of body-weight was entirely satisfactory in the light of new statistical and pharmacological practice There was some discussion, but he remained unanswered

CLINICAL TRIALS

Prof A Bradford Hill said that it was just as well that the newer statistical techniques, which were so valuable for extracting the maximum amount of information from data, had not been available ten years ago, when the scientific basis of therapeutic trials was being established, for it was doubtful whether clinicians would have tolerated them Now, however, with the principles of clinical trials widely accepted, it was possible to introduce newer techniques, such as sequential analysis, without astonishing physicians too much

Prof W A Bain discussed the design of small-scale drug trials and pointed out that with careful design a great deal of valuable information could often be obtained from a very few patients Since subjects for clinical trials of new drugs might be very scarce it was vitally important to attend carefully to design if many drugs were to be tested at all

Dr Richard Doll discussed some practical problems of the design of clinical trials—in particular the necessity for controls, including the use of dummy drugs Randomisation was important, allotting of patients or treatments alternately had serious disadvantages

Finally, Dr T F Fox spoke on the ethics of experiments on man

He pointed out that patients must be able to rely on a doctor doing what was best for *them*—not what he thought best for other clients, or for himself, or for his profession, or for science On the other hand, to deserve the trust of the public, doctors must have knowledge, and their duty to advance knowledge could not be fulfilled without clinical experiment A clear distinction must be drawn between the sick person as patient (to whom nothing must be done except to his direct advantage) and the sick person as volunteer (a legitimate object of experiment) This change of status required the person's consent If, before entering hospital, patients had read a printed explanation mentioning the need for experimentation, perhaps they could be regarded as having given implicit consent for penicillins are used In a recent W H O survey of over 600,000 patients, there was only 1 death from penicillin in 70,000 treated, and in the W H O -assisted venereal-disease-control programme in Taiwan there was only 1 death in 44,000 treated

Many of the severe reactions have arisen in persons with a previous history of allergy, especially to penicillin It was suggested that many fatalities can be avoided if a careful preliminary history is taken Important in the prevention of such reactions is the restriction of the use of the drug to only well-established indications and of its sale to the production of a doctor's prescription (antibiotics may be bought over the counter in many countries of the Western Pacific region) Some deaths can be prevented by resuscitating drugs, and all doctors who administer penicillin should have on hand an emergency kit containing appropriate syringes, adrenaline, nikethamide, hydrocortisone, an anti-histamine drug for injection, aminophylline, and, if available, penicillinase

LIVER DISEASES

A symposium on liver diseases was held in Lund and Malmo, Sweden, on March 28 and 29, under the joint presidency of Prof J P Sandblom and Prof J Waldenstrom

Dr H Vetter (Austria) described the use of radioactive colloid materials in the estimation of liver blood-flow This is based on the assumption that these substances are removed from the circulating blood by the cells of the reticulo-endothelial system, which are mostly found in the liver This removal is estimated by simply placing a counter between the thighs Suitable radioactive substances are colloidal radiogold and heat-denatured human serum-albumin labelled with ^{131}I In cirrhosis of the liver, comparison of results obtained with colloidal radiogold with those for bromsulphalein showed that two-thirds of the diminished bromsulphalein removal was due to decreased liver blood-flow and not to impaired liver-cell function There was a significant negative correlation between the liver blood-flow and the portal venous pressure

Galactose is metabolised solely by the liver, and Dr N Tygstrup and Dr K Winkler (Denmark) had given this compound intravenously and measured its removal from the blood Liver blood-flow was then calculated Quite small amounts of alcohol diminished galactose removal The mechanisms of this interference were obscure

Dr R L Blomstrand (Sweden) had cannulated the thoracic duct and studied the lymph biochemically 10–50% of the thoracic-duct flow comes from the liver The normal flow was 40–120 ml an hour A patient with cirrhosis produced 500 ml an hour This overproduction would support the hypothesis that ascites is produced from liver lymph Erythrocytes injected into the ascites could be recovered from thoracic-duct lymph

Dr C E Ekman and Professor Sandblom reported their results for portocaval anastomosis in cirrhotic patients with portal hypertension 11 of 69 patients died after operation Preoperative tests showed that 9 of those dying had poor liver function and 2 good liver function This emphasised the importance of reserving this operation for those with good hepatic reserve 42 of 55 survived one year and only 2 had further gastrointestinal hæmorrhage

QUANTITATIVE METHODS IN HUMAN PHARMACOLOGY

A symposium on Quantitative Methods in Human Pharmacology and Therapeutics, arranged by the Coordinating Committee for Symposia on Drugs and supported by the British Pharmacological Society, the Physiological Society, the Royal Society of Medicine, and the Biometric and Nutrition Societies, was held in London on March 24 and 25

Sir Charles Harington remarked that it had been said that the invasion of biology by mathematics had robbed it of much of its charm But the quantitative aspects of biology were vitally important, and those who, like himself, hankered after the days when workers could be content with qualitative observations had to recognise that this feeling was a weakness to be sternly suppressed sanctity of human life man comes from the earth and will return to it as though he had never been, and he has no rights beyond these which the State confers on him It is at least logical that if man exists for the State, the State has the right to do whatever is expedient with him It is not illogical for Lenin to write "Three-quarters of mankind must die if necessary, to ensure the other quarter for Communism" Such an ethic has foundations in basic beliefs about the nature of man—however untrue those beliefs may be

What a difference from humanism! The contrast lies in humanism's high estimate of man. Its aim is to gain the greatest development for every human being, and this by education, not by force Much of the noblest effort and achievement, such as liberal education and modern democracy, has sprung from this exalted view And yet these two, Communism and humanism, are alike in one major aspect they both deny the supernatural and God In denying God, humanism builds its ethics on sand "Ought" and "ought not" are words that have real content and meaning only for those who recognise an Authority who can make absolute demands on them The "ought" of humanism is the consensus of humanitarian opinion, the sanction of expediency and public taste We are not ignorant of the force of propaganda and indoctrination to change these standards—and to rationalise the change In this lies the danger of accepting our clinical ethics from the borrowed capital of humanism

If one doubts the possibility of our ethics being changed by circumstances, and those changes being accepted by medical and other humanitarian people, one has only to consider Germany in our own time This sad example shows how our accepted standards can be lost if we hold them loosely and without adequate reason. As T S Eliot has said, "If you remove from the word 'human' all that belief in the supernatural has given to man, you can view him finally as no more than an extremely clever, adaptable and mischievous little animal" In spite of humanism's high estimate of man, the inhumanity of man to man has never been more obvious than it is to this generation

The shallowness of some contemporary writing on medical ethics, said Mr Jackson, is the failure to follow through to basic concepts of the nature of God and man Our accepted ethics of clinical research are of Christian origin, being based on the nature of man and the value of his life in God's sight. The extent and growth of totalitarian ideologies make it clear that we cannot assume that our present standards are either self-evident or unlikely to be assailed There is no safety in standing on "the uncertain sands of past traditions, or that ever-changing contemporary belief—the consensus of humanitarian opinion"

SENIOR REGISTRARS

Correspondence between Minister of Health and Chairman of Joint Consultants Committee

The Joint Consultants Committee and representatives of the Ministry of Health have been jointly considering the future of the time-expired senior registrars The Joint Committee found themselves unable to agree to proposals put forward by the Ministry, and asked to see the Minister of Health. The planning subcommittee of the Joint Committee, led by Sir Russell Brain, met the Minister on March 25 In the course of a full discussion the Minister said, among other things, that present economic conditions obviously made it difficult to contemplate any substantial increase in the consultant establishment. The Joint Committee, later the same day, considered the result of this meeting and asked Sir Russell Brain to see the Minister again for further discussions Sir Russell met the Minister on April 1, and the Minister promised to comment in writing on the views of the Joint Committee Subsequently the following letters were exchanged

9th April, 1958

Dear Sir Russell,

When we had our talk about senior registrars on the 1st April I said I would write to you on the points you raised and let you know the lines of the statement I am proposing to make to Parliament after the Recess

You told me that the Joint Committee were not happy about the creation of a new grade which would consist of people some of whom might not become consultants From this it appears that I cannot have made my proposals quite clear I know the Committee's views about the creation of a new grade, and though I do not share them, my proposals are deliberately drawn to deal with the immediate problem of the time-expired senior registrars in a reasonable way without raising the contentious issue of a new grade

The whole plan of the draft circular put to the Committee last year was to make reasonable provision for these time-expired men in senior registrar posts, not in posts of some new grade The fact that the extended salary scale envisaged by the draft circular would be attached to a limited number of senior registrar posts, not to all, does not conflict with that concept At the same time the plan avoids the difficulty presented by the suggestion that has been made that all senior registrars who do not obtain a higher appointment within their normal term of training or within a defined period of its completion should automatically become entitled to a higher salary As I explained in the course of our conversation, an arrangement of this kind would be a simple inflationary salary increase and not consonant with the Government's policy Moreover, it would be wrong to change the salary scale for senior registrar posts generally while the Royal Commission is in the midst of its enquiry into remuneration

Similar considerations stand in the way of arranging that all senior registrars who fail to secure a consultant post within a reasonable time would be put in the senior hospital medical officer grade If, however, the proposition were that the designated posts envisaged by the draft circular should be in the senior hospital medical officer grade instead of in the senior registrar grade the same difficulties would not apply—though, as you said, there might well be others Before I could say whether such a proposition would be acceptable I should need to be given fairly full details, including information of the modifications which would be proposed to the agreement of 1950 on senior hospital medical officer posts For the time being, therefore, I think we should keep to the idea of making suitable provision in senior registrar posts

The suggestion that senior registrars who were doing consultant work might forthwith be given consultant status but not the pay of consultants, and be assured that they would be given a consultant appointment when economic and other circumstances allowed, does not seem to me to offer an acceptable solution to the difficulty and I should have expected that this applied from the Joint Committee's angle just as much as from mine We do not want the posts occupied by these time-expired senior registrars to be regarded as a substitute for additional consultant posts This is stressed in the draft circular What we have in mind, as I have said, is that they would still occupy posts which entail work proper to the senior registrar grade, and designated posts involving work commensurate with that which is normally expected of a fourth year senior registrar would carry the extended salary scale The holders would be able to continue to compete for consultant vacancies and no doubt they would do so This is now the established method of obtaining consultant status, and I am sure that it is the method that serves the best interests of the hospital service—which must be the paramount consideration—and must be maintained intact for that reason minor procedures carrying virtually no risk and causing little discomfort. But, even so, the decision about these procedures should be taken by the doctor who had undertaken to look after the patient and therefore to put his interests first (called by Guttentag the " physician-friend "). When an experiment was more than trivial, the " physician-experimenter " (whose chief concern was to solve a problem) should be a different person from the physician-friend, and the consent must be explicit not implicit. It must also be valid, and, if the patient could not understand what was proposed, supplementary consent should be obtained from a medical person acting on his behalf, preferably his family doctor.

In the discussion one or two speakers regarded it as impracticable and undesirable to separate " experimenter " and " friend " the patient, they felt, was best safeguarded if the experimenter was personally and fully responsible to his patient. Dr Fox, however, thought that the vision of investigators, when engaged in experiments, was liable to become so concentrated and limited that they could not suitably take decisions on the patient's behalf. Decisions could be very difficult, and, if an experiment was doubtfully justifiable, the experimenter could properly be questioned by his peers when he reported his work to a society. Medical journals, too, might properly ask authors to include specific assurances that the patients were true volunteers, and it was professionally healthy that clinical experiments should occasionally be challenged publicly by those who found them disturbing.

Dr J van Noordwijk gave an account of an official Dutch study of the ethics of human experimentation. Several workers explained their experiments, and invited Dr Fox to comment on their ethical position—which, as an outsider, he declined to do. The questions showed that clinical workers are conscious of the perennial difficulties facing those who try to advance knowledge by working on man.

The proceedings of the symposium are to be published by the Pergamon Press, London.

Special Articles

MORAL RESPONSIBILITY IN CLINICAL RESEARCH

Mr D MacG Jackson, surgeon to the Birmingham Accident Hospital, spoke on this subject at a London meeting of the Christian Medical Fellowship on March 26.

Research, he said, is a new departure in medicine, with the future in mind there is no reference to it in the Hippocratic Oath. It may take the form of " observation " or " planned experiment ", or both, but experiment is a sharper tool—it has been compared to cross-examining Nature rather than merely overhearing her. Though experimental clinical research will probably always remain the call of a few, these should have the fullest understanding and willing cooperation of their clinical colleagues, because research is a moral responsibility of all doctors. As McCance has remarked, without continued research our knowledge would fall away as it did in the Middle Ages and be forgotten. For those who have qualms about the value and propriety of clinical research, the answer to inhuman research is humane research—not no research at all.

The greatest interest in the morality of clinical research is shown by the public, who realise the importance of interpersonal relationships with doctors. In practising clinical research there is an obvious conflict of loyalties which is not shared in purely medical work. The physician's care is focused first, last, and all the time on his patients, but the good investigator must be very much interested in his problem. There are many other loyalties, however, common to both these men, which conflict with that to their patients—responsibilities for teaching, for their families, for their livelihood, their own health and recreation, and perhaps for Christian, social, or political work. The investigator has just one more loyalty to which he must give correct priority—loyalty to his particular search for the truth.

F H K Green has pointed out that " when the value of a treatment, new or old, is doubtful, there may be a higher moral obligation to test it critically than to continue to prescribe it year-in-year-out with the support merely of custom or of wishful thinking. In this sort of test there are few limiting moral considerations, for it is indicated only when both of two (or more) treatments are unevaluated. Moreover, frequently there will be no indication to get the patient's permission for inclusion in such a trial. Again, various clinical " experiments "—such as taking a few extra millilitres of blood at the time of a diagnostic or therapeutic venepuncture—are not uncommonly done without obtaining permission. This is done and accepted in the spirit of good faith embodied in the doctor-patient relationship. But if the experiment is more elaborate, involving any degree of extra discomfort, risk, or cooperation, most investigators would agree that the whole procedure should be explained to the patient or parent honestly and fully, and their permission obtained. At the same time, explanation is often difficult, and because of the patient's trust in the doctor he may agree to almost anything. Hence consent, though it should be obtained, is not enough. The responsibility for an experiment rests squarely on the investigator and each member of his team at all times, and if there is any doubt the value and propriety of the trial should be considered by informed and independent opinions.

Remarking that the real difficulty lies in the application of our principles, Mr Jackson devoted the closing part of his address to " a much more neglected aspect of this subject "—namely, the source of the accepted moral responsibilities of clinicians.

The underlying concepts are, first, a belief in the sanctity of human life, and secondly a belief that the claims of the individual come before those of the society in which he lives. What is the source of these concepts? Are we still prepared to accept them, and if so, why?

The Greek world showed neither compassion nor organised care for the weak, the disabled or the hopeless case. In India, Hinduism is fundamentally a philosophy of denial of this world and life, and till recently there was no active expression of love and compassion to those in need. The earliest Buddhist hospitals in India preceded by some 400 years the first Christian hospitals, for Buddha advocated merciful action to those suffering. But, though kindness is at the centre of Buddhism, a sick man is not of value as a personality. Kindness is for the benefit of the doer rather than the sufferer, and a man's first and chief occupation is with his own redemption. In China the height of medical development was reached about the same time as that in India, but under the influence of Confucius subjection to authority produced a fatal inertia which turned tradition into a prison.

The Christian view of man is in contrast to these, and is based on the two teachings of the *Old Testament* that man is a creature created by God, and that man is made in the image of God. Linked with these two ideas is the appreciation of man as an individual each individual is unique. In contrast to the indifferent and fatalistic view of suffering reflected in Greek and Roman and in Eastern religions, Christ gave us a new estimate of the value of human life and personality. In no other religion are these basic values found, though the fruits of them are coveted and copied.

Many would accept our medical ethics as self-evidently good, while divorcing them from their foundation principles. But this is a dangerous and superficial attitude. If we feel that our present clinical ethical code is the best, it is short-sighted, if not madness, to regard it as self-evident. It is not so regarded by believers in Marxist ideology which is extending its influence now over one-third of the population of the world. Marxian Communism denies the existence of God and the sanctity of human life: man comes from the earth and will return to it as though he had never been, and he has no rights beyond these which the State confers on him. It is at least logical that if man exists for the State, the State has the right to do whatever is expedient with him. It is not illogical for Lenin to write "Three-quarters of mankind must die if necessary, to ensure the other quarter for Communism." Such an ethic has foundations in basic beliefs about the nature of man—however untrue those beliefs may be.

What a difference from humanism! The contrast lies in humanism's high estimate of man. Its aim is to gain the greatest development for every human being, and this by education, not by force. Much of the noblest effort and achievement, such as liberal education and modern democracy, has sprung from this exalted view. And yet these two, Communism and humanism, are alike in one major aspect: they both deny the supernatural and God. In denying God, humanism builds its ethics on sand. "Ought" and "ought not" are words that have real content and meaning only for those who recognise an Authority who can make absolute demands on them. The "ought" of humanism is the consensus of humanitarian opinion, the sanction of expediency and public taste. We are not ignorant of the force of propaganda and indoctrination to change these standards—and to rationalise the change. In this lies the danger of accepting our clinical ethics from the borrowed capital of humanism.

If one doubts the possibility of our ethics being changed by circumstances, and those changes being accepted by medical and other humanitarian people, one has only to consider Germany in our own time. This sad example shows how our accepted standards can be lost if we hold them loosely and without adequate reason. As T. S. Eliot has said, "If you remove from the word 'human' all that belief in the supernatural has given to man, you can view him finally as no more than an extremely clever, adaptable and mischievous little animal." In spite of humanism's high estimate of man, the inhumanity of man to man has never been more obvious than *it is to this generation.*

The shallowness of some contemporary writing on medical ethics, said Mr. Jackson, is the failure to follow through to basic concepts of the nature of God and man. Our accepted ethics of clinical research are of Christian origin, being based on the nature of man and the value of his life in God's sight. The extent and growth of totalitarian ideologies make it clear that we cannot assume that our present standards are either self-evident or unlikely to be assailed. There is no safety in standing on "the uncertain sands of past traditions, or that ever-changing contemporary belief—the consensus of humanitarian opinion."

SENIOR REGISTRARS

Correspondence between Minister of Health and Chairman of Joint Consultants Committee

THE Joint Consultants Committee and representatives of the Ministry of Health have been jointly considering the future of the time-expired senior registrars. The Joint Committee found themselves unable to agree to proposals put forward by the Ministry, and asked to see the Minister of Health. The planning subcommittee of the Joint Committee, led by Sir Russell Brain, met the Minister on March 25. In the course of a full discussion the Minister said, among other things, that present economic conditions obviously made it difficult to contemplate any substantial increase in the consultant establishment. The Joint Committee, later the same day, considered the result of this meeting and asked Sir Russell Brain to see the Minister again for further discussions. Sir Russell met the Minister on April 1, and the Minister promised to comment in writing on the views of the Joint Committee. Subsequently the following letters were exchanged.

9th April, 1958.

Dear Sir Russell,

When we had our talk about senior registrars on the 1st April I said I would write to you on the points you raised and let you know the lines of the statement I am proposing to make to Parliament after the Recess.

You told me that the Joint Committee were not happy about the creation of a new grade which would consist of people some of whom might not become consultants. From this it appears that I cannot have made my proposals quite clear. I know the Committee's views about the creation of a new grade, and though I do not share them, my proposals are deliberately drawn to deal with the immediate problem of the time-expired senior registrars in a reasonable way without raising the contentious issue of a new grade.

The whole plan of the draft circular put to the Committee last year was to make reasonable provision for these time-expired men in senior registrar posts, not in posts of some new grade. The fact that the extended salary scale envisaged by the draft circular would be attached to a limited number of senior registrar posts, not to all, does not conflict with that concept. At the same time the plan avoids the difficulty presented by the suggestion that has been made that all senior registrars who do not obtain a higher appointment within their normal term of training or within a defined period of its completion should automatically become entitled to a higher salary. As I explained in the course of our conversation, an arrangement of this kind would be a simple inflationary salary increase and not consonant with the Government's policy. Moreover, it would be wrong to change the salary scale for senior registrar posts generally while the Royal Commission is in the midst of its enquiry into remuneration.

Similar considerations stand in the way of arranging that all senior registrars who fail to secure a consultant post within a reasonable time would be put in the senior hospital medical officer grade. If, however, the proposition were that the designated posts envisaged by the draft circular should be in the senior hospital medical officer grade instead of in the senior registrar grade the same difficulties would not apply—though, as you said, there might well be others. Before I could say whether such a proposition would be acceptable I should need to be given fairly full details, including information of the modifications which would be proposed to the agreement of 1950 on senior hospital medical officer posts. For the time being, therefore, I think we should keep to the idea of making suitable provision in senior registrar posts.

The suggestion that senior registrars who were doing consultant work might forthwith be given consultant status but not the pay of consultants, and be assured that they would be given a consultant appointment when economic and other circumstances allowed, does not seem to me to offer an acceptable solution to the difficulty and I should have expected that this applied from the Joint Committee's angle just as much as from mine. We do not want the posts occupied by these time-expired senior registrars to be regarded as a substitute for additional consultant posts. This is stressed in the draft circular. What we have in mind, as I have said, is that they would still occupy posts which entail work proper to the senior registrar grade, and designated posts involving work commensurate with that which is normally expected of a fourth year senior registrar would carry the extended salary scale. The holders would be able to continue to compete for consultant vacancies and no doubt they would do so. This is now the established method of obtaining consultant status, and I am sure that it is the method that serves the best interests of the hospital service—which must be the paramount consideration—and must be maintained intact for that reason.

and also in fairness to other potential competitors for consultant posts

The terms and conditions of service do not exclude the possibility of a hospital doctor holding a part-time consultant appointment and a part-time senior registrar appointment at the same time and indeed instances exist, though they are few, of doctors holding part-time appointments in the senior registrar grade and in another grade at the same time Any extension of arrangements of this kind would depend on Boards splitting sessions which they would otherwise group for one consultant appointment and assumes that geographical considerations are no impediment This would make for administrative complication and would increase expense For these reasons I do not think that it would be appropriate positively to encourage the growth of this kind of arrangement, certainly not in advance of the Working Party's report

My general approach to the problem of the time-expired senior registrars is that we should set up a Working Party to study, in the light of experience of the hospital service since 1948, and of all other relevant considerations, the principles on which the medical staffing structure in the hospital service should be organised, and that pending the Working Party's report we should make reasonable provision for the time-expired men I am not seeking to bring about some permanent change in the staffing structure by these interim arrangements I fully accept that the arrangements should be regarded by both sides as of an interim nature pending decisions on the Working Party's recommendations, and I hope that with this explicit assurance the Joint Committee may feel able to accept in principle the suggestions set out in the draft circular for dealing with the immediate problem The way will then be clear for the details of the circular to be settled, and for the Working Party to be got under way

As you know I am committed to making a statement to Parliament immediately after the Recess The enclosed note shows what I have in mind Settlement of its final terms must await the outcome of your meeting on the 16th No doubt I shall be hearing from you as soon as the meeting is over? I think the Members who are taking a special interest in this will be counting on my making a statement on the 21st

Yours sincerely,
DEREK WALKER-SMITH

16th April, 1958

Dear Minister,

The Joint Consultants Committee has considered the discussion which some of its members had with you on March 25th and your letter to me dated 9th April, 1958 The Committee welcomes your proposal of a joint working party with the Ministry to study, in the light of experience of the hospital service since 1948 and of all other relevant considerations, the principles on which the medical staffing structure in the hospital service should be organised A recent answer which you gave to a question in the House of Commons shows what a wide discrepancy there is in the consultant establishments in certain specialties between different regions It seems to us therefore necessary to enquire how this has come about and whether the needs of the service for consultants are being fulfilled Such an enquiry by the proposed Working Party would call for a survey for this purpose We have long thought that the work done by S H M O s is in need of review and the Working Party should, and we understand would, include in its scope the consideration of the work of S H M O s, including the points which Whitley Committee B recently decided to investigate

With regard to the time-expired senior registrars we believe on a number of grounds that the only satisfactory solution of this urgent problem is that these doctors, who have long completed their training for consultant posts, should obtain such posts, but the establishment of new consultant posts must of course be related to the needs of the service, which the Working Party is to consider It seems to us more logical and practical to await the recommendations of the Working Party, which we hope will be available within a year, than at once to create new senior registrar posts which, carrying the implication that they may be permanent, are likely to prove equally unattractive to senior registrars and to hospital management committees If there should ultimately be some of the present time-expired senior registrars who do not in the end obtain consultant posts we accept the principle that such people should, if they wish, be given permanent security in the Health Service This principle being accepted, we think that the kind of work they should do needs most careful consideration by the Working Party and should not be the subject of an immediate decision, the full implications of which cannot now be foreseen For this reason we are unable to accept the principles set out in the draft circular, but if you decide nevertheless to proceed with your proposals to create these new posts we think that their terms and conditions should be discussed with us either in the Working Party or by direct consultation between the Ministry and the Joint Committee We understand that the Working Party will be free subsequently to make what recommendations it thinks fit with regard to their future, subject to the provision of the same security of tenure for the holders We regard it as an important part of its subsequent task to see that this situation does not recur

As our discussions with you cover more points than are dealt with in this correspondence we assume that an agreed statement covering our discussions will be published together with these letters

Yours sincerely,
W RUSSELL BRAIN

18th April, 1958

Dear Sir Russell,

Thank you for your letter of 16th April I was glad to note that the Joint Consultants Committee welcome my proposal of the joint working party with the Ministry to study, in the light of the experience of the hospital service since 1948 and of all other relevant considerations, the principles on which the medical staffing structure in the hospital service should be organised The working party would of course cover the whole staffing structure and in the case of Senior Hospital Medical Officers I see no objection to its dealing with the points which Committee " B " of the Medical Whitley Council have recently decided to investigate, always providing that there is no objection from Committee " B " itself Of course I do not envisage that the working party will deal with pay

I can understand that holding the views they do the Committee would prefer to leave over the problem of special posts for time-expired senior registrars until the working party has completed its report But, as I have said, my proposal is purely an interim one and although we all hope that the working party will be able to complete their task within a year, the problems are complicated and I am sure that neither of us would want consideration of the very difficult questions that will arise to be hindered by pressure to produce a speedy report because of the immediate problems of individual time-expired senior registrars Nor do I think that these individuals should have to wait on the working party for some further assistance with their present position

I enclose a draft of the statement I propose to make in reply to a question which has been put down for answer on the 21st I hope you will not find that this will raise difficulty on your side

Subject to the last paragraph of the statement, I shall be very glad for the terms and conditions of the new posts to be further discussed between the Ministry and the Joint Committee, but for the above reasons we really must come to a speedy decision

I shall of course see no objection to this correspondence being published if you wish

Yours sincerely,
DEREK WALKER-SMITH

⁂ The statement by the Minister in the House of Commons on April 21 is reproduced on p 906 —ED L

Public Health

THE HEIGHTS AND WEIGHTS OF EDUCATIONALLY SUBNORMAL CHILDREN

A PARRY JONES
M B Wales, D P H
DEPUTY MEDICAL OFFICER OF HEALTH, CHELTENHAM, GLOS

W MURRAY
HEADMASTER, THIRLESTAINE COURT E.S N SCHOOL, CHELTENHAM

THE 1944 Education Act has helped to revolutionise the approach to the education of the handicapped child The main type of handicap is mental backwardness, and, since 1945, 153 special schools for educationally subnormal (E S N) children have been opened in England and Wales,[1] more being planned for the immediate future

Admission to these schools is generally on the grounds of mental backwardness—i e , poor scholastic attainment combined with a low intelligence quotient (50–75) But we noticed that often the children were also backward *physically*, though there was seldom any disease to account for their physical retardation This apparent difference was such that we decided on a detailed investigation, and accordingly we measured the heights, weights, and intelligence quotients of the children attending two junior E.S N day schools in neighbouring towns

In presenting our findings we have used the height and weight indices of Sutcliffe and Canham[2] These indices numerically resemble intelligence quotients (the normal being 100), and we have used them so that our measurements can be readily compared with those of normal children.

Sutcliffe and Canham compiled their figures from the heights and weights of seventeen thousand boys and girls in various parts of England, including our own. These tables have a possible disadvantage in that they were compiled in 1948, and we wondered whether they might be out of date So we took the average heights and weights of the children seen at school medical inspections during the last year and converted them into Sutcliffe and Canham indices The readings varied from the normal of 100 up to 103 Hence we regard these indices as satisfactory for the purposes of this investigation

TABLE I—HEIGHTS OF E.S N CHILDREN (BOYS AND GIRLS COMBINED)

Age (yr)	Height index								Total
	Below 70	70	80	90	100	110	120	130 or more	
7	—	—	1	1	—	—	—	—	2
8	1	2	5	1	1	3	1	—	14
9	1	3	6	7	5	1	—	—	23
10	2	4	3	7	5	3	1	—	25
11	3	3	8	5	2	1	1	1	24
12	3	1	5	9	9	1	—	—	28
13	1	1	3	—	3	1	1	—	10
Total	11	14	31	30	25	10	4	1	126

Tables I and II show that 73% of the children attending these E S N schools had weight indices below the normal of 100, and that 68% were also below the average in height. Whereas with normal children the majority of heights and weights fall within 90–110 on this index scale, with these E S N children the majority fell within 80–100 both in height and weight. Among the remainder, more children were at the lower end of the scale than at the higher Thus we are in no doubt that there is a considerable difference in physique between normal children and those in our two E S N schools

We did not detect any significant difference between the measurements of the boys and those of the girls The degree of underdevelopment was spread evenly between all age-groups except the youngest, in which the number of children examined was small

We do not claim that these observations are original More than twenty years ago Burt found that the dull and the intrinsically backward suffered primarily from retarded (physical) development[3] In 1941 Boas[4] wrote of American children

TABLE II—WEIGHTS OF E.S N CHILDREN (BOYS AND GIRLS COMBINED)

Age (yr)	Weight index								Total
	Below 70	70	80	90	100	110	120	130 or more	
7	—	—	—	1	1	—	—	—	2
8	1	1	4	2	—	4	—	2	14
9	—	2	5	9	4	1	2	—	23
10	3	3	7	5	4	3	—	—	25
11	2	2	9	7	1	—	1	2	24
12	2	3	5	9	6	1	1	1	28
13	2	3	4	1	—	—	—	—	10
Total	10	14	34	34	16	9	4	5	126

> "A study of the data collected shows an unexpectedly high relation between intelligence quotients and stature. Children short for their age had an I Q markedly under the norm, those tall for their age, one above the norm "

Recently the standard of living in this country has risen, but in our E S N schools the findings are much the same as those of Burt twenty years earlier This might suggest that the relation between physical and mental retardation is independent of environment, but we think that the more likely explanation is that these recent social improvements are not in fact reaching all children Certainly many of the E.S N children under our care have not benefited as fully as might be expected In some homes laziness and thoughtless spending of money may lead to an unnecessary lowering of standards which adversely affects the children

We do not wish to imply that a poor home environment is necessarily a major cause of the poor physique of E S N children This is a problem that has not yet been disentangled Burt[3] wonders how far this physical and mental difference between the bright and the dull

> "is due to the direct effect of a healthy life and diet upon the manifestations of intelligence, as judged by the ordinary tests, how far it is due to the fact that the more intelligent families are both able and willing to give better attention to hygienic conditions, and how far it is an outcome of a fundamental impulse to grow more rapidly in all directions "

An answer might be forthcoming if direct additional feeding could be provided for these underdeveloped children With the expansion of the special-school programme as a result of the 1944 Education Act, more and more E.S N children are being segregated The experiment of direct additional feeding would now be administratively easier, and the effects, if any, could be more readily measured In our opinion the provision of extra food and milk in E.S N schools would be well worth trying, and the results might be rewarding

The views expressed here are our own and are not necessarily those of the Cheltenham Committee for Education

Poliomyelitis Vaccine

In written replies on Monday to questions about the supply of poliomyelitis vaccine, the Minister of Health said that about $6^1/_2$ million doses of vaccine were needed for the programme of vaccinating pregnant women and children under 15, towards this, 2 million doses were in the hands of local authorities by the end of February Orders had been placed with two British firms and (for 5000 litres of Salk vaccine) with one United States and one Canadian firm For different reasons there was a hold-up in supply in each of the four sources When the first difficulties arose in the supply of British vaccine, a further 2800 litres of Salk vaccine had been ordered, as well as further supplies when the Salk vaccine due last week did not appear Some British vaccine was now being distributed, and, barring further unforeseen difficulties, much larger supplies (mainly of Salk vaccine) would be ready next month Further supplies of Salk vaccine were being ordered The Indian Government had imposed certain restrictions on the export of monkeys, but these had not so far interfered with the manufacture or testing of vaccine in this country

A batch of vaccine (250,000 doses) from the Wellcome Foundation was held up by sickness of the test monkeys, this batch has now been passed and distribution has begun According to press reports, the Canadian source, Connaught Laboratories, believe that there has been a "misunderstanding in London" the contract was for 4 million doses before the end of June, and half of this had been supplied, the director knew that the British authorities wanted extra supplies in March, but the domestic demand had been exceptionally heavy just then The United States source, the Pitman-Moore Company of Indianapolis, said that 1,300,000 doses destined for Britain were held up because 1 virus out of 50,000,000 in a testing sample was found to be alive

A batch has arrived in London for testing of the consignment of 1,500,000 doses ordered as an emergency from the Parke Davis Company of Detroit A large proportion of this is said to be in stock and to have passed the tests of the company and the United States authorities The British tests normally take about $2^1/_2$ months

Case of Smallpox in the Wirral

A boy, aged 2 years, who lives about 400 yards from New Ferry Smallpox Hospital (where a seaman is lying ill with smallpox [1]), and who had not been vaccinated, fell ill on April 6 A rash appeared on April 9 and by April 14 was profuse all over the trunk, arms, and legs, and confluent on the face, the palms and soles were affected Asian smallpox was confirmed Since an attack of mumps he had not been out till about March 22, and then in a wheel chair There were few contacts outside the home All contacts have been vaccinated and are under surveillance, his relations living at home are remaining indoors, and their shopping is being done by a health visitor The child was admitted to New Ferry Hospital, and on April 20 was reported to be much better

New Recommendations in Industrial Diseases

The Industrial Diseases Advisory Council was asked to review all the diseases prescribed under the Industrial Injuries Acts (except pneumoconiosis and byssinosis), and its subcommittee has now issued a report,[2] with recommendations, which have been accepted by the Minister of Pensions and National Insurance

The Council suggest an inquiry into elbow conditions in trades involving manual labour They recommend that the description of poisonings by certain substances (e g , lead, benzene) should be extended to certain of their compounds, and that there should be changes in the definitions of industrial dermatitis and radiation injuries Slight changes were recommended in the wording concerning the cover provided for tuberculosis

Parliament

Opticians Bill

At the report stage of this Bill [1] an amendment was accepted adding a fourth ophthalmic specialist to the General Optical Council, thus raising the number of medical representatives from 5 to 6

In moving the third reading of the Bill Mr **Richard Thompson**, parliamentary secretary to the Ministry of Health, said that it left the House in better shape than when it was introduced The promoters had accepted modifications to meet the views of the House The Bill now provided that the register of ophthalmic opticians should be in two parts, those proposing to test sight only and those proposing to test sight and to dispense glasses Amendments had also been accepted which prohibited the testing of sight except by a registered medical practitioner or a registered ophthalmic optician, and the sale of optical appliances except by or under the supervision of a doctor or optician An amendment had been added defining the scope of the optician's work in relation to the work of the medical practitioner Mr Thompson was glad that it had been found possible to introduce wording into the Bill which defined these responsibilities satisfactorily It was important that the optician should not overstep the boundary between his functions and those of the doctor He looked forward to a constructive partnership between opticians and doctors in the future as a result of the Bill and of the setting up of the General Optical Council

QUESTION TIME

Senior Registrars

Mr **Kenneth Robinson** asked the Minister of Health if he would now make his promised statement on the senior registrar problem —Mr **Derek Walker-Smith** replied The Joint Consultants Committee and I have agreed to set up a joint working party to study, in the light of experience of the hospital service since 1948 and of all other relevant considerations, the principles on which the medical staffing structure in the hospital service should be organised

I have concluded that—pending and without prejudice to the working party's report—the current arrangements for senior registrar posts should be modified in certain respects, in view of the fact that some senior registrars have long completed the normal tenure of their posts but have not yet succeeded in obtaining a higher post I am satisfied that these senior registrars should be given an opportunity of remaining in the hospital service whilst they continue to compete for higher posts, and hospital boards are being asked where necessary to offer extended contracts pending the working party's report

Also without prejudice to the working party's report, I am asking hospital boards to submit proposals for designating a limited number of senior registrar posts—mainly from among those already existing—which will provide responsible work commensurate with that which is normally expected of a fourth year senior registrar, will carry a higher rate of pay, will offer security of tenure, and will be available to senior registrars who have completed the normal period of appointment in the grade The senior registrars selected for these posts will of course be free to continue to compete for higher appointments I will emphasise to boards that these senior registrar posts are not to be regarded as a substitute for additional consultant posts

The Secretary of State for Scotland is discussing with the Scottish Joint Consultants Committee the application of these arrangements to Scotland

Mr **Robinson** Is the Minister aware that the interim arrangements which he has announced may be a satisfactory solution to the short-term problem, but that the only tolerable solution to the long-term problem is a considerable expansion of consultant posts? Why is it necessary to set up a working party to come to that very obvious conclusion? Mr Walker-Smith We have to look at the number of consultant posts which are desirable in the light of the staffing structure, and also of the economic context I hope that we shall get a quick and valuable report from this working party, and I prefer to wait for that

---

[1] See *Lancet*, 1957, ii, 1166 & 1234

Sir Keith Joseph Will the Minister note that it is not commonly accepted that the only long-term solution is an expansion of the consultant force, since the economics of the service to the public and the location of the consultants in relation to the public demand that those factors must be examined most carefully? Mr Walker-Smith I will certainly bear in mind those valuable and constructive suggestions

Dr Edith Summerskill All that the Minister has said today is that the matter is to be postponed once more, and that the anxiety of these senior registrars is to continue for an indefinite period Is he aware that these men are being offered excellent opportunities in the United States of America, and that if there is to be another postponement we shall lose some of the best doctors in the country?—Mr Walker-Smith From the right hon. Lady's purported precis of my answer, I am afraid that either she did not hear or did not understand what I said If she will be good enough to read it, she will find that there is a great deal more for the senior registrars than she has said

Merit Awards Committee

Mr Robinson asked the Minister what was the size of the committee on merit awards to consultants of which Lord Moran was the chairman, and how many of its members were psychiatrists —Mr Walker-Smith replied 14, besides the chairman and the lay vice-chairman. None is a psychiatrist. Mr Robinson Without necessarily drawing the conclusion that the abysmally low number of merit awards to psychiatrists is connected with their non-representation on the committee, does not the Minister agree that this important specialty should be represented on the committee? If the Royal College of Physicians is unwilling to nominate a psychiatrist, will the Minister instruct the committee to seek nominations from the Royal Medico-Psychological Association?—Mr Walker-Smith In this matter I follow the recommendations of the Spens report, that the members of the awards committee should be appointed from nominations made by the Royal Colleges, the Scottish Royal Corporations, the Medical Research Council, and the universities The nominations of those bodies are in personal capacities and not representative of specialties

Russian Vaccine for Multiple Sclerosis

Mr Somerville Hastings asked the Minister if he had any further statement to make regarding the Russian vaccine for multiple sclerosis, notably its toxicity —Mr Walker-Smith Not yet, but inquiries are being pursued Mr Hastings Is the Minister aware that a certain amount of recent research has been carried out in Belfast, which associates this vaccine with rabies and that this has given rise to a very great deal of anxiety in the minds of the public?—Mr Walker-Smith It has recently been established that the vaccine is made from the brains of rats or mice infected with the rabies virus No further evidence is available as to the safety of the vaccine in treatment, but research is going on.

Dr Summerskill As a question of this kind was put to the Minister very many weeks ago and he assured us then that he was looking into the matter, why has it taken him such a long time? He must recognise that during this time many patients suffering from disseminated sclerosis have been waiting hopefully for some statement from him.—Mr Walker-Smith I have not been inactive in that matter I was asked to look into the New Zealand question, which I have done No evidence of the efficacy of the vaccine is available from there I am seeking information from the Russians through the appropriate channels Therefore, my position is at present that I can agree to the release of small private imports of this vaccine, but the patients' doctors in those cases have to agree to accept responsibility for the treatment.

Regional Distribution of Consultants

The numbers of consultants and other medical staff (including whole-time, part-time, and honorary staff) in hospitals under the regional hospital boards at the end of 1956 were given in whole-time equivalents in a written answer on April 15 and are shown in the second and third columns of the following table The estimated number of staffed beds and population in each region, given in the fourth and fifth columns, are taken from an earlier answer[1]

Regional hospital board	Consultants	Other medical staff*	Number of staffed beds (excluding beds allocated to mental illness and mental deficiency)	Estimated population (in thousands)
Newcastle	332	352	15,338	2944
Leeds	232	334	17,753	3066
Sheffield	285	456	19 716	4230
East Anglian	121	136	7254	1485
N W Metropolitan	420	641	17,930	3942
N E Metropolitan	317	502	18,966	3103
S.E Metropolitan	355	439	19,933	3229

Medicine and the Law

Doctor Charged with Manslaughter

At an inquest at Bridgend, Glamorgan, a coroner's jury returned a verdict of manslaughter on the ground of reckless negligence by a doctor[2]

In evidence, the doctor said that a woman of 39 consulted him on Dec 2, "six days before she had a miscarriage", but that he saw her next day (Dec 3) and "then discovered that she had had something done to her" The doctor thought that she was on the verge of pneumonia, and not that she had septicæmia She was under his sole care from Dec 8 to Dec. 23, he called in no other doctor She died in hospital from septicæmia At the first consultation she had asked the doctor to end her pregnancy, and he had refused

After the inquest the doctor was formally charged and granted bail

Death of a Boxer

A verdict of death by misadventure was recorded, at a Manchester inquest on April 17, on a boxer who died after lying in semicoma for 321 days following a contest.

The boxer, aged 23, was said to have collapsed in the dressing-room soon after the bout, in the last round of which he was sent down with two blows to the chin He had been warned that, because of a head injury sustained in a contest in the Army, he should never box again, but he went on with his boxing career

Two operations had been attempted on the man's brain At necropsy, there was no fracture of the skull, and the surface of the brain showed no evidence of laceration The meninges were thickened and stained yellow, indicating previous hæmorrhage, there was no trace of a blood-clot Death had been due to bronchopneumonia following internal hydrocephalus caused by traumatic subdural and subarachnoid hæmorrhages A pathologist said that the condition could have been caused by a blow on the jaw, this was comparatively rare, but "quite a number" of cases had been reported

In England Now

A Running Commentary by Peripatetic Correspondents

"AND there," said the Salesman, turning a handle round and round, "after one minute you have all the vegetables cleaned and peeled and ready for cooking No messy peelings to deal with, every scrap goes down the sink, and what's more, for storage you just slap it against any wall and the suction feet keep it there " Suitably impressed, we returned home a few bob lighter, clutching our shining new 'Veg-O-Lux' I suppose the fault was really in us and ours rather than in the machine When the Architect, in powdered wig and knee-breeches, supervised the erection of our house he didn't bargain for a veg-o-lux

The Salesman couldn't understand why the sink had got blocked up, but he sold us a handy little chap called the 'Basin-Unstoppa' guaranteed to recanalise the most recalcitrant thrombosis Much encouraged, we returned to the leguminous battle and all went well until the time came for disposal we slapped it gaily on the kitchen wall and the sucker feet brought four tiles straight off This time the Salesman got rid of a tin of 'Tile-U-Up' When the thing brought down a shelf, he sold us some 'Neva-Slip' brackets

The whole episode to me had a familiar pharmaceutical ring Drugs tend to procreate themselves in just the same way Get a good new tablet and before the end of the year there are four or five others in use to counter its side-effects Either that, or it procreates a long line of modifications, side-chain derivatives, analogues, and so on Then the bubble bursts and you are back to square one It happened with liver extracts and it's happening now with tranquillisers (and not before time) All Life moves in cycles if not indeed in circles, though perhaps we like to think ourselves a little further on each time I suppose we usually are It remains to be seen whether this vegetabular circle has helped much after all, it seems that vacuum cleaners are being superseded by the revolutionary new carpet sweepers that require no electricity and do not harm the pile, my wife, too, finds more and more clothes that she prefers to wash by hand instead of subjecting them to the eviscerations of the washing machine At this rate by 1960 we shall be cooking our meals over an open fire in the back garden yes—and may be that's not so funny

* * *

Since the publication of the paper by Douthwaite on Pitfalls in Medicine,[1] I have been considering writing a companion paper on Medicine in Pitfalls

The telephone rings at 4 30 A M "Would I come at once —three men buried " I pull on my old gardening clothes and set off for the pit The Manager is waiting and tells me that one man got clear and two are buried I put on pit boots and helmet and we set off for the shaft through the crowd of men at the shift change The van from the mines rescue station with emergency surgical equipment arrives, the driver tooting rather importantly as he drives through the crowd We get our lamps, arrange for a haulage lad to carry the equipment, and then drop down half a mile Underground, an official meets us with the latest news One man is almost clear, they have located the other and he seems to be alive We set off for the coal-face and quite near it meet the stretcher party with the first man He appears to be in reasonable shape with a possible fractured ankle I ask the first-aid man to treat it as a fracture and send him out We dump our main equipment and start to crawl down the face with a small emergency bag The face height is about 3 ft 6 in, but the effective height is reduced because it has been prepared for "filling" and is obstructed by much newly blown down coal

The fall begins about 30 yd along the face The Manager leads, and when we get near he says "There seems to be some groaning and moaning, have a look at him " I find myself in a space about 3 ft wide with a nasty dark void above and the fall in front The man is trapped now only up to his knees and two men are digging away cautiously to free him There is no room for anyone else By the time I have given some morphine he is free We drag him under a good roof and find that although tired and weak he seems to have no gross injuries A stretcher is pushed up and the waiting helpers carry him along the face This is an awkward task because of the restricted height and rough floor His main complaint is that the pieces of string he used to keep up his socks are cutting into his swollen legs This is easily put right and he is covered up ready for the journey to the pit bottom

At this stage a grinning toothless veteran speaks to him "How are ye, Jim?" he says "They didn't make all this b—— fuss when I were buried "

* * *

My score for doctors on the Aldermaston march was higher than that recorded by my peripatetic colleague last week I counted eight—a physician, a surgeon, a pædiatrician, a virologist, a Colonial medical officer, and three G PS The last group included me, the only one to go all the way—in my car which was bespattered with red crosses *My patients* (what a pity I don't practise in London, Middlesex, Bucks, and Berks, they could all have been temporaries) were many—some with exhaustion, a couple of faintings, a dozen sprained ankles, two chickenpoxes, and over three hundred pairs of blistered feet

* * *

Nowadays one rarely has the opportunity to describe a new clinical syndrome, and only my inherent modesty prevents me from calling mine by my own name (Also the fact that I am reserving my name for my Nobel prize-winning effort) Alternatively I could name the syndrome after the first person to manifest the new disease But one of the patients was born in Poland and his name is unpronouncable, and to call it Addison's disease after my second patient would only lead to confusion So rather reluctantly I have been forced to adopt the old dermatological device of using a descriptive name, and the name I have finally selected is "Subacute phenindione pigmentary palmosis" There are two varieties var sinistra, and var dextra, the latter being the more common form

Curiously enough, though phenindione (var 'Dindevan') has been in clinical use for some years I have only lately seen my first 2 cases of S P P P Both patients complained of a patchy orange yellow discoloration of the right palm It did not itch nor was it found anywhere else Both patients had tried to wash it off without success and both were much perturbed by the phenomenon One had even travelled five miles to hospital especially to consult me about it They were both familiar with the orange-yellow pigmentation which is seen in (alkaline) urine and which could be confused with the colour produced by blood But neither of them had spotted that their disease arose from their habit of holding the pills in their right hand before swallowing them By passive transfer tests—i.e , holding the bottle in the other hand—I was easily able to transfer the disease to the opposite palm This was a much more elegant method of demonstrating its origin than by holding the tablet itself and brought home the point that it was advisable to empty the pills into a spoon

Several points remain to be elucidated Why has the syndrome not been spotted for so many years—after all we have been using phenindione for quite a while Is it only dindevan that does it? What of 'Hedulin' and 'Indema', which as far as I know are different trade names for the same substance? Is it associated with the alkaline tide of meals and only found in those who take their pills some time *after* a meal, or can it occur in those taking their pills while in a fasting state? All these points are at present under intensive investigation* and I hope one day to publish a further report on this new and fascinating syndrome Confirmatory reports are awaited with interest

* * *

Yesterday I received through the mail a small long-playing record from an American pharmaceutical firm One side recorded a one-year clinical study of the firm's newest preparation; the other the Vienna State Opera Orchestra playing Brahms' *Hungarian Dances* The drug advertised is a tranquilliser

Letters to the Editor

ADMINISTRATIVE THERAPY

Sir,—You are to be congratulated on your foresight in accepting, and giving pride of place in last week's issue to, Dr Clark's excellent paper

The subject is in its infancy and the paper gives a clear account of matters upon which the future success or failure of the psychiatric hospitals and perhaps the general hospitals of this country may depend

These matters have until now been bedevilled by national and local politics, the Ministry need for control through biddable men, the wild individualism of hospital medical staffs, and the now notorious and non-merited epitaph of so many medical superintendents "Administration does not count"

It is hoped that Dr Clark's paper will arouse interest in the subject at a date early enough to prevent the present generation of administrative therapists, administrative psychiatrists, medical superintendents, or whatever name they go by, being the last of their kind, for unless sufficient interest is aroused the treatment of the patient as a member of a group, which in the hospital he is, will be disregarded, psychiatry, covering nearly 50% of all hospital beds, will become the appendage of business management, and it is for the consideration of general hospital medical staffs that already they have travelled far along this road

Prudhoe and Monkton Hospital,
Prudhoe-on-Tyne

George McCoull
President, Medical
Superintendents Society

Sir,—Dr Clark, in his second last paragraph, says " the most important task of the administrative therapist is to establish the atmosphere of the hospital He needs openness, consistency, respect for everyone's human dignity, and a welcome for everyone's contribution "

This is very true I think it is a pity, however, that this is the nearest that Dr Clark gets to facing the fact that senior medical staff, by which I mean consultants and S H M O s, must take part in the administration of the mental hospital and must share with the superintendent in the making of policy decisions if the hospital is to work at its maximum efficiency This fact seems to me to be recognised in the Ministry's recommendation that medical advisory committees, consisting of senior medical staff, should advise hospital management committees and regional hospital boards Surely this implies that senior medical staff share with the medical superintendent ultimate responsibility for every aspect of hospital functioning They certainly cannot discharge this responsibility unless they share in the making of policy decisions

The tendency of consultants to indulge in " the flight into treatment ", which Dr Clark describes, may very well be a manifestation of the " apathy and withdrawal " described by Schwartz as occurring in groups deprived of the responsibility attaching to their position

I also regret that Dr Clark appears to believe that "As he [a medical administrator] treats his staff so will they treat the patients " This statement is self-evidently untrue But perhaps Dr Clark is merely saying again what he has said earlier in his article—that disturbed relationships between senior medical staff result in disturbed relationships between nursing staff and patients

Shenley Hospital, near St Albans

D Bardon

THE FUTURE OF THE PUBLIC HEALTH LABORATORY SERVICE

Sir,—The answer to A Provincial Pathologist (April 12) is that despite the millions of pounds spent annually, and largely wasted, on antibiotics, and the serious problem of hospital infection, bacteriology is not recognised as a specialty in the National Health Service in England and Wales The only bacteriologists connected with the hospital service are the select band employed by the universities in the medical schools If a bacteriologist wishes to obtain a post in the National Health Service he has to do so in the guise of a general pathologist or an assistant pathologist and work under the direction of a consultant pathologist-in-charge who is either a morbid anatomist and cares nothing for bacteriology, or a clinical pathologist who thinks he knows it all (as well as hæmatology, clinical biochemistry, surgical histology, and forensic pathology)

If A Provincial Pathologist studies the literature he will know that nearly all the significant contributions to medical bacteriology in the past ten years have been made by workers outside the National Health Service If he studies the advertised vacancies he will see that the only advertisements for hospital bacteriologists come from Scotland, where there is a more enlightened view of the importance of bacteriology in the diagnosis and treatment of infective disease and the control of hospital infection

A London Bacteriologist

TOXÆMIA OF PREGNANCY

Sir,—Professor Theobald (April 12), by casting algebraic pebbles into the ripples of the toxæmic clinical pattern, cannot obscure the design whose periphery on occasion develops into the eclamptic wave, despite the prophylactic antenatal oil applied to the surface of the pool to still its waters

His classification of the toxæmic state correctly interpreted reflects the normally mounting severity of the underlying renal changes responsible for the production of, at first, the œdema (a result of the reduction of the glomerular filtration), next, the hypertension (a result of cortical renal ischæmia), and, finally, the albuminuria (a result of the slowing down of the renal circulation) In fact his data, unwittingly, further support the renal intervention, by demonstrating that a severe degree of renal ischæmia if prolonged leaves its stigma on the kidney in close resemblance to the experimental effect of sufficiently prolonged clamping of the renal artery in animals, in whom irreversible renal changes are thereby produced His data also offers proof of the uterorenal reflex, for by denervation of the uterus and interruption, thereby, of the uterorenal pathway he has succeeded in preventing toxæmia—an achievement for which he deserves the highest credit, if I may be permitted so to judge

Conjecture of disharmonious function of various hormones in the ætiology of toxæmia has no validity in fact or by inference from available data Such disharmony cannot be advanced to explain postpartum hypertension and proteinuria, which already find satisfactory explanation on the basis of the uterorenal reflex[1] Although Professor Theobald admits the intrusion of an inadequate blood-supply to the placenta as being of ætiological significance, he completely fails to appreciate the influence of the resistance to stretch of the uterine muscle in provoking it and thereby overlooks the stimulus responsible for the uterorenal reflex that by imposing renal ischæmia causes the toxæmic manifestations

The impact of geography and diet are those of superimposed effects on the ætiology, acting either for good or for ill They can be so assessed inasmuch as they help to influence the size and the chemical constitution of the body compartments, which in their turn benefit or impede the renal function disturbed by the pre-eclamptic process

SALT IN PREGNANCY

SIR,—Dr Robinson (Jan 25) undoubtedly showed great moral courage, for she must have realised from the first that she would cause among obstetricians feelings of shock, surprise, and even disbelief, when stating that she treated 20 patients with toxæmia of pregnancy, with good result, by allowing them extra salt

It is this part of her investigation that interests me most Personally I regret that Dr Robinson did not measure the aldosterone output during periods of salt-free diet and compare it with the output during periods when extra salt was given

According to prevailing opinion, when extra salt is given the production and urinary output of aldosterone diminish, the same may be true of the quantities of aldosterone stored in the adrenal cortex, so that when this and other hormones are suddenly liberated from the adrenals (e g, by histamine produced by an antigen-antibody reaction) smaller quantities of hormones are available and ultimately reach the circulation, which circumstance must have a favourable influence on the course of toxæmia

However, Dr Robinson's results are so unexpected that I quite agree with Dr Thomas (April 12, p 793) that it is of the utmost importance to verify or challenge these results, because they may very well modify our therapeutic concept of toxæmia of pregnancy

Amsterdam R SCHUURMANS

ONE RADIOGRAPH TO EXCLUDE PLACENTA PRÆVIA

SIR,—Dr Earn and his colleagues in your issue of April 19 have done well to draw attention to the efficacy of soft-tissue placentography in excluding placenta prævia One wonders though if they have not oversimplified the picture

Given ideal conditions one tilted standing lateral view of the uterus and pelvic brim is enough to diagnose placenta prævia or exclude it where the radiographic signs are definite But not infrequently conditions are not ideal and then the signs may be indefinite Intestinal stasis and an abundance of gas that accompany rest in bed will often interfere with accurate interpretation Around 34 weeks too the smallness of the fœtal head may allow the existence of a minor though significant degree of placenta prævia without much displacement Even slight hydramnios may be enough at this stage to make diagnosis indefinite

But what your contributors have failed to stress is the great need for the fœtus to be lying axially with one or other pole centrally over the brim at the time of the X-ray It is the responsibility of the obstetrician to see to this and to be present at the radiographic examination for this purpose—otherwise a useless and misleading film may be taken and the patient and fœtus needlessly exposed

When we published[1] the results of 275 placentograms in your journal in 1955 we stated that the error should be nil if the diagnosis "border-line placenta prævia" in doubtful cases is used We made 3 errors in diagnosing 50 placenta prævias—none serious In our next 275 placentograms there were 40 placenta prævias with 1 diagnostic error due to a thin membranaceous placenta prævia Thus in 550 placentograms for diagnosing 90 placenta prævias the error was less than 1%, the combined fœtal mortality (corrected) for placenta prævia was 8 8% and there was no maternal death The 17% error of your contributors for placenta prævia we feel is much too high and is in danger of detracting from the merits of an accurate technique

We think that soft-tissue placentography is a very reliable method so long as proper regard is given to its basic principles One radiograph certainly should be the aim though not always achieved (it has been ours for some time past), and for this reason all possible care should be given to both choice of the patient and suitability of the fœtal lie

The London Hospital, E 1

ROBERT PERCIVAL
STANLEY MURRAY

SIR,—I cannot entirely agree with Dr Earn and his colleagues that a single lateral radiograph of the uterus is sufficient to exclude placenta prævia Admittedly they would be correct in the vast majority of cases, but there is one fallacy which they appear to have overlooked I have now had more than ten years' experience of this method, and on several occasions I have found normal appearances in the lateral radiograph with evidence of placenta prævia—sometimes of a major degree—only in the anteroposterior view taken in the semi-erect position

Harrogate FRANK REID

SUPPORT FOR THE FAMILY

SIR,—In your leading article of April 5, you stated that as a result of my survey of old age in Bethnal Green, I had put forward the suggestion of a constant attendance allowance to be offered to relatives who undertake the care of bedridden old people In fact I suggested that the allowance might be payable not to relatives but to bedridden pensioners themselves, this was only one of a number of recommendations put rather summarily at the end of a book devoted to the family life of people of pensionable age

I found that the strongest and most enduring relationships between adults in a family were those between people who gave a great deal to each other, every day as well as in emergencies If her daughter had a paid job a grandmother often prepared meals and looked after one or more of the grandchildren (whether or not they lived with her) while the married daughter, for her part, did the shopping and heavy cleaning Old people were invariably less happy when they could no longer "do their share" and contribute materially to a relationship It seems there may be three or four bedridden old people at home for every one in hospital or residential home Too often a relative bears the strains of nursing with little support, while the old person has no opportunity of useful occupation or of making the relationship of dependence less one-sided This is why I argued that an allowance should be paid to the old person rather than to the relative He or she may then be in a better position to pay independently for any special needs and to repay the relative for the care given Of course, many practical questions relating to a "personal attendance allowance" would remain unanswered in thus settling a matter of principle by appeal to the findings of one sociological investigation

EPIDEMIOLOGICAL INQUIRIES

SIR,—Working in the field of health education, we are very dependent on the findings of epidemiology, but being accustomed to think that the knowledge and attitudes of the people concerned may be a vital factor in the epidemiology, we are often disappointed that it is not generally taken into account

I am at present engaged in working out an epidemiological inquiry card which, in addition to the usual information about personal and environmental factors, is intended to include questions regarding recognition of the condition by the population at risk, knowledge about the condition, attitudes towards it, and finally behaviour regarding it

As I am sure other workers have considered this point, and as I am particularly aware of the difficulty of validating such questions, I should be glad if you would give me space to ask any who are interested or who have trodden this path, to communicate with me

THE DOCTOR'S ATTITUDE TO HIS PATIENT

SIR,—Although it is hardly possible to have the Rev John Wesley read Scanner's letter (April 12) ("The emotional history should not have any direct influence on the doctor's clinical opinion the clinician reaches that opinion without the emotional history, and can give just as good advice and can get just as good a result without ever hearing it"), we must hope that Scanner's patients will insist that he reads the Journal of the Rev John Wesley "Whence came this woman's pain (which she would never have told had she never been questioned about it)? Why, then, do not all physicians consider how far bodily disorders are caused or influenced by the mind?" (*Lancet*, April 12, p 763)

T

CORONARY-ARTERY DISEASE

SIR,—In your editorial (March 22) Horlick and Craig[1] are quoted as showing that "in some subjects such an action [specific cholesterol-lowering effect] was seen on giving ethyl linoleate and linoleic acid in pure form"

While it is true that when ethyl linoleate was substituted for the mixed fats of the normal diet, the serum-cholesterol fell, we also noted that when ethyl linoleate was given to an individual on a low-fat diet whose cholesterol levels had stabilised, there was no further fall in cholesterol We concluded that ethyl linoleate possessed no specific cholesterol-lowering effect and that effects observed with it were due to the removal of animal fats from the diet when isocaloric diets containing linoleate were prepared Our results differ from those of Kinsell et al[2] who reported that linoleate lowered the blood-cholesterol of subjects on a low-fat diet

Careful perusal of their data (2 cases) shows that in case 1 (27-year-old male with familial hypercholesterolæmia) the serum-cholesterol fell from a level of 326 on the low-fat diet to a level of 291 at the end of seven days on 80 g of ethyl linoleate daily In their second case (19-year-old male with fractured femur) the cholesterol fell from 145 at the end of two weeks on a fat-free diet to 95 after one week on 80 g of linoleate per day

Considering the rather wide fluctuations in day-to-day cholesterol levels seen in both of these subjects the results can only be considered significant in the second subject It should be noted that whereas our subjects were healthy and mobile, carrying on their regular work as medical students, Dr Kinsell's subject was immobilised with a healing fracture It is conceivable that such differences may influence the results obtained

Because of the scanty data available, I believe that it would be premature to draw any conclusions concerning the role of essential fatty acids in cholesterol metabolism and atherogenesis

LONG-TERM ANTICOAGULANT THERAPY FOR CORONARY-ARTERY DISEASE

SIR,—Your leading article (Feb 22) gives the impression that a novel simplified technique has been devised by Manchester[1] to solve the problem of venepuncture for the multiple prothrombin tests required This impression is quite erroneous (and Manchester[2] himself does not subscribe to this notion), since similar techniques were suggested by Quick[3] and Kato[4] for assessing prothrombin deficiency in infants We[5] adopted the better components of these procedures and, using a modification of a method[6] for freeze-drying thromboplastin, elaborated a simplified technique using capillary whole blood In effect, all the operator has to do is to reconstitute the dried brain extract with water and mix 0 02 ml of it with an equal volume of capillary blood and note the clotting-time We claimed no originality for the test, but recommended its use by the practitioner, when laboratory facilities for the usual one-stage prothrombin method during anticoagulant therapy were not available.

Our students are instructed in the capillary technique, because many will become practitioners in the country away from laboratory facilities The method became so popular that, when long-term anticoagulant therapy was instituted in Dr Suzman's unit at the Johannesburg General Hospital, it was used in controlling therapy in outpatients Today over 50 estimations are done at the weekly follow-up prothrombin index (P I) clinic, and the first detailed analysis of the results was published by my colleagues[7] who, together with others, speak highly of the method This report deals with 82 cases treated continuously with anticoagulants for periods up to seventy-six months

Although the simplified technique has been known for a long time it is surprising that it has not been applied more generally When our paper was abstracted by Brown,[8] he rightly criticised us for not having provided more statistical analysis than the bare coefficient of correlation of 0 82 between the capillary method and the usual laboratory method However, he misinterpreted our caution in applying the method for general use in anticoagulant therapy as an indication that the technique was inaccurate We were concerned that the method might be used for the "prothrombin response to vitamin K" test in the differentiation of intrahepatic and extrahepatic jaundice,[9] and so bring this diagnostic test into disrepute However, the deviation between the capillary and intravenous methods can be considerably reduced by practice and is no longer a hindrance to the acceptance of the procedure for the control of anticoagulant therapy

[9] Stein, H B *S Afr J med Sci* 1942, 7, 72, *ibid* 1944, 9, 111

In their authoritative book on blood-coagulation, Biggs and Macfarlane[10] also dismiss microtechniques as not being sufficiently reliable Our own tendency to exercise caution in recommending the capillary method is due to the fact that no laboratory worker will voluntarily substitute it for the usual Quick[11] technique, I myself[12] have written disparagingly of "bed-side" procedures for estimating prothrombin, since it is impossible to perform multiple tests on the same sample or to control the temperature and other conditions of the test However, mass-production demands simplified methods of control, and the experience of the local outpatient P I clinic shows that the method is one in which skill is soon acquired by attentive medical registrars and house-physicians

At one end of the scale of one-stage prothrombin methods there are simplified capillary techniques, and at the other the relatively complicated "prothrombin and proconvertin" method of Owren and Aas[13] All the methods require care and attention to technical details, of which the most important is the concentration and standardisation[14] of the only significant reagent used in the test—namely, tissue (brain) thromboplastin

TRANSTHORACIC LIGATURE OF ŒSOPHAGEAL VARICES

SIR,—In my book, Portal Hypertension, I appended the name of George Crile, Jr, to the operation of transthoracic ligature of œsophageal varices because I believe that he was the first to describe it adequately It has never been my intention to give the impression that Dr Crile himself had written the chapter, as suggested by the review in your issue of April 12 The chapter was written by me and the methods are strictly my own, following what I understand to be those of Dr Crile I sincerely hope that Dr Crile will forgive me for any misunderstanding that may have arisen

London, W 1

ALAN H HUNT

*** We ask Dr Crile's forgiveness for our part in this misunderstanding —ED L

THE HARVARD STEP TEST

SIR,—There appears to be some disagreement among experts as to how this test should be conducted

In *The Physiology of Muscular Exercise* by Schneider and Karpovich and in *Circuit Training* by Morgan and Adamson, it is stated that pulse readings should be taken 1–1½ mins, 2–2½ mins, and 4–4½ mins after 5 minutes of step-ups Other books by Larsen, McCloy, Clarke, and Reidman quote the time for pulse readings as 1–1½ mins, 2–2½ mins, and 3–3½ mins It appears therefore that there are two separate tests In an endeavour to find which, in fact, is the Harvard step test I wrote to the American Association for Health, Physical Education and Recreation They have confirmed that Dr Lucien Brouha, of Harvard University, advocates the second method quoted above, and sent me a reprint, from the *Research Quarterly*, of an address delivered at Springfield College entitled The Step Test—A Simple Method of Measuring Physical Fitness for Muscular Work in Young Men This is dated December, 1942

It does not seem to matter much which test is used as both are an effective way of measuring cardiovascular fitness What does, however, matter is to know, when comparisons are being made between the physical-fitness indices of well-known athletes, that the results quoted have been computed in the same manner if a fair comparison is to be made I believe that the Amateur Athletic Association's coaches have been testing athletes in this country and using the first method of testing and not the recognised method of conducting the Harvard step test

An authoritative statement on the correct method of conducting this test and computing the physical-fitness index would be most welcome and a great help to physical educationists and athletic coaches

St Luke's College, Exeter

W R CAMPBELL

RADIATION, LEUKÆMIA, AND MALIGNANT DISEASE

SIR,—An important point has been lost sight of in the strenuous correspondence concerning the communication by Dr Alice Stewart and her colleagues,[1] regarding the relationship of radiation, leukæmia, and malignant disease the paper was a *preliminary* communication Dr Stewart, one imagines, was so concerned at the possible importance of their initial findings that this publication was submitted at once, surely it is equally admirable that the Editor of *The Lancet* commented upon it in an editorial[2] A preliminary communication means what it says, and as one of those who has been most generously and courteously allowed to see some of the data, may I endorse the pleas of you and Dr Stewart to wait and see After such attacks it can be understood that the final report will be being very carefully prepared

I could not help raising my eyebrows at Dr Jackson's accusation (March 29) that Mr Hewitt has "merely found what he sought" I am afraid that perhaps Dr Jackson does not wish to find what he may see

FRANK FALKNER

TREATMENT OF OBESITY

SIR,—Dr Mullins' letter of April 5 on the perennial problem of the overweight rightly points out the dangers of obesity and the advantages of reducing to normal limits In theory the majority of overweight patients reducing intake by a diet lose weight In practice for a variety of reasons it is not so easy for the individual to stick to a diet Help is needed, but I am surprised to find she considers strict supervision is essential, as this is contrary to my experience on the whole

For a number of years I have been employing weight reduction methods using only hydrophilic colloids These are given ½ to 1 hour before normal mealtimes in the form of liquid preparations which "deceive" the stomach and produce an effective anorexia (One of these methods suitable for hospital use is described elsewhere[3]) In the few cases of apparent failure or partial failure almost all such patients admitted that they had not followed instructions, had been casual about them, or had decided they no longer wished to reduce Only in such cases does strict supervision become imperative

I note that Dr Mullins uses various drugs, some of them very potent, in her supervised regime However, in many cases reducing can and ought to be carried out in the patient's home, and if this is to be done without strict supervision certain essential conditions must be observed The criteria which seem important to me when considering a "weight-off" method are (1) complete freedom from danger, non-toxicity, and complete absence of side-effects (thus, in my opinion, rules out the use of potent “ drugs ”), (2) efficiency of action, (3) simplicity of use, (4) low cost, (5) that the rationale should be capable of convincing translation into a simple story which the patient can appreciate—this I consider most necessary in gaining the patient’s full cooperation Certain of the hydrophilic colloid group fulfil these criteria admirably and are capable of preparation at low cost in hospital pharmacies However weight reduction methods are “ modish ” creatures In 1912 there were at least 24 proprietory “ treatments ” [4] all of which have fallen by the wayside Today a dozen or so methods come to mind including 3 or 4 potent drugs, and in the future we shall no doubt meet new variations of method

USE AND TOXICITY OF SULPHONAMIDES

SIR,—It is good that Dr Arneil (April 19) has sounded what I hope will be the death knell of that dangerous drug, sulphamerazine

It is good, too, that in your annotation you emphasise the value and safety of sulphadimidine Alas though, too many doctors only know of this drug as ‘ Sulphamezathine ’ which, to the ear, sounds little different from sulphamerazine I have often found it necessary, when recommending the use of sulphadimidine, to add the proprietary name by way of explanation

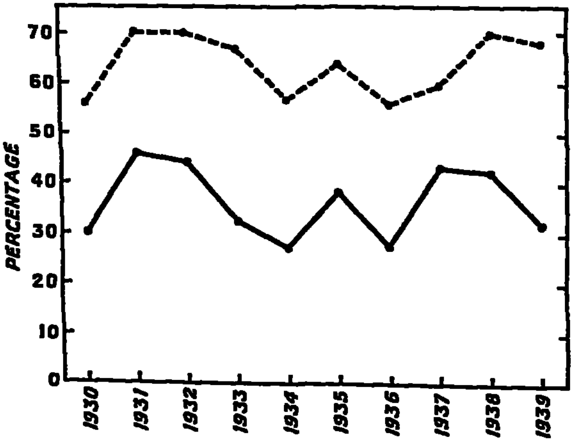
Cannot the manufacturers suggest a way of avoiding this confusion? Greater prominence of the official *B.P* name on their labels would help

Derby BERNARD M LAURANCE

TREATMENT OF BREAST CANCER

SIR,—Mr. Bond and Dr Waterhouse (Feb 22) and Dr George Crile, Jr (April 5) are correct in implying that “ the strong challenge from the Mayo Clinic ” is indeed no challenge at all, except perhaps to those folk who seem unable to assess the proper significance of published figures Your editorial certainly presents the Mayo Clinic figures in somewhat tendentious fashion, and though you find it difficult to compare “ figures from the Mayo Clinic and those from Edinburgh ” one is glad to see that your correspondents do not experience the same difficulty

The close correlation between survival-rate and the stage of the disease is well brought out in the accompanying figure from a series of 1044 cases seen at St Bartholomew’s Hospital [5] The figure shows the crude five-year survival-rate for patients with breast cancer registered between 1930 and 1939 inclusive Also shown is the percentage of cases placed in clinical stages I and II each year The graph of survival-rate is closely paralleled by that of the clinical staging, and this figure is analogous to that shown in Mr Bond and Dr Waterhouse’s letter



1044 cases of breast cancer Continuous line—5-year-survival rate in all cases registered Broken line—percentage of cases in clinical stages I and II

The age-distribution of the patients is also relevant in the comparison of different series, yet you make no mention of this point Even in the absence of this information about the Mayo Clinic series, it would seem that the figures do no more than support the maxim that the apparently good results are mainly, if not wholly, the results of selection

Radlett, Herts REGINALD S MURLEY

NEW METHOD OF PHENOBARBITONE ADMINISTRATION

SIR,—Although my experience here is limited to one “ hystero-epileptic ” patient, and a period of four weeks, Dr Pearson’s (April 19, p 853) critical comments on Dr O’Connor’s innovation (March 22, p 609) prompt me to say that this patient (who over the last two years proved impervious to any form of therapy) has changed beyond recognition since being put on phenobarbitone ‘ Spansules ’

Wyke House Hospital,
Isleworth, Middlesex H PULLAR-STRECKER

FLEXION SPASMS AND CONTRACTURES IN SPINAL-CORD DISEASE

SIR,—My interest in the paper by Mr Platt, Dr Ritchie Russell, and Dr Willison (April 12) prompts me to make the following comments on some of their statements

It is indeed gratifying that clinicians are becoming more and more aware of the various intrinsic and extrinsic factors that influence spasticity in patients suffering from spinal-cord afflictions, and, in this connection, the beneficial effect of utilising postural reflexes in the counteraction of flexor spasms, as postulated by previous workers, is confirmed by the authors

On the other hand, their sweeping statement that, in cases of spinal-cord disease causing severe paraplegia, a day or two in bed may lead to permanent loss of all capacity to be other than chair-ridden or even bed-fast is, to say the least, exaggerated, if not altogether misleading Furthermore, I was surprised to read the authors’ criticism of anterior rhizotomy of lumbar and sacral roots for relieving spasticity by claiming that it produces such wasting of gluteal muscles that sitting becomes uncomfortable This view will hardly be acceptable to neurosurgeons who have had experience with this method, nor is it in accordance with the vast experience gained on patients with conus/cauda-equina lesions or residual paralysis following poliomyelitis If anterior rhizotomy is contemplated in patients where severe and intractable spasms and contractures of the hip flexors and adductors are predominant, complete atrophy of the gluteal muscles can be avoided by sparing L4 or L5 roots

Judging from the immediate postoperative condition of their third case, following their technique of combined bilateral obturator resection and iliopsoas resection in one session, it is obvious that their procedure is no less formidable and hazardous to the patient than anterior rhizotomy, and anyone contemplating this type of operation would be well advised to carry it out in stages

The authors, in the techniques of physical therapy described, have very closely followed the principles and details of treatment introduced and practised during the last 14 years in the National Spinal Injuries Centre, Stoke Mandeville, and have freely used its resources In their description of their first case, whom I had the opportunity to see myself in consultation, I missed any reference to the remarkable beneficial effects of hydrotherapy in our swimming-pool—not only as an overall training effect but, indeed, in this particular case, as a most efficient method of relieving spasticity Moreover, this patient is photographed in a walking-chair which I designed a few years ago specifically for exercises for paraplegics with complete or incomplete lesions I assume that the authors did not realise that this design had not been published (it will be described in detail elsewhere), as they would otherwise no doubt have made due reference

LUDWIG GUTTMANN

*** This letter has been shown to Mr Platt and his colleagues, who write "We are sorry that Dr Guttman is so critical of our methods of treating flexion spasms and contractures Our approach to the problem differs in several respects from those which he has developed so successfully for cases of traumatic paraplegia, but we think he will find that the method now described proves to have some important advantages We were unaware that the walking-chair used to support the patient for the photograph had any special features"—ED L

SIR GEORGE SAVAGE AND THE SANDS OF TIME

SIR,—I saw a good deal of Sir George Savage (1842-1921), as my father was virtually an old Guy's man and a personal friend of Addison, who presented him with a copy of his bust that used to stand in the hall of his house in Grosvenor Street

Savage contributed many interesting articles, written for the students, to the *Guy's Hospital Gazette*, which I eagerly read, as my father continued to be a subscriber to the *Gazette* until his death One of the articles that fascinated me was entitled The Sands of Time, and I think it ought not to be forgotten It described some of the mental troubles of old people, and fancifully compared the mind of an old person to the sands on a desert, blown about by the wind A storm would blow away the top layer of sand and expose an underlying layer, which might be taken to correspond to a fanciful memory of remorse for having once stolen a sixpenny piece as a boy A fresh storm might expose another layer, which unfortunately corresponded to the memory of having once told his father a falsehood At last fresh winds might arise and cause a new layer to be reached, which fortunately corresponded to one of the happiest memories of his life

London, N W 1

F PARKES WEBER

INFANTILE GASTROENTERITIS

SIR,—The answers to many of Dr Librach's questions (April 5) relating to fundamental work on infantile intestinal flora are to be found in various articles [1–5] as well as textbooks of pædiatrics and bacteriology

Dr Librach is no doubt aware that many commensals (including *Escherichia coli*) are pathogenic outside their normal habitat, and that some are potentially so in their own systems—e g, pneumococci and staphylococci in the respiratory tract In this example there is a further similarity to *Esch coli* gastroenteritis in so far as certain types (or strains) of these organisms are involved more than others in the production of pneumonia

In all infections the host plays an important role In the case of gastroenteritis, favourable living conditions in the small bowel for *Esch coli* are provided by the diet of cow's milk (the carbohydrate protein ratio amongst other factors) With regard to transmission, the agents in intestinal infections (including viruses) enter the bowel usually by mouth, at which they may arrive in many ways, and there seems to be no reason to doubt that infection with *Esch coli* is acquired in the same way as with shigellæ and salmonellæ

It seems to me that the interpretation of the presence in fæces of an "enteric" virus, which may be as widely distributed as *Esch coli*, would present almost the same problems as exist with the serotypes of *Esch coli* in question, which have been associated consistently with the disease (if I may call it so) at least since the 1920s [6] Finally, for a comprehensive account of the ætiology I would refer Dr Librach to the Royal College of Physicians of Edinburgh Publication no 5 [7]

City Hospital, Greenbank Drive,

G SANGSTER

POSTOPERATIVE HYPOTENSION

SIR,—As you say (March 15), postoperative hypotension is relatively common, and it is seen particularly in patients returned to the horizontal from the lithotomy position

In 176 cases of major vaginal surgery, a significant degree of hypotension was found in 101 (57%) [8] Of a series of 75 cases of anæsthesia for perurethral prostatectomy, which I hope to publish later, in 36 (48%) the systolic pressure fell to below 100 mm Hg, or to a level more than 50 mm Hg below the preoperative level, when the legs were lowered

As you also say, routine recording of the blood-pressure after operations is not common practice Quite a number of the above patients had none of the recognised signs of hypotension Indeed, they had an easily palpable pulse at a rate within normal limits they were dry, warm, and of good colour, and they were conscious and cooperative

The dangers that beset these patients may be illustrated by two cases

Both patients, on return to the ward, appeared so well to the nurse that they were propped up to encourage drinking Both quickly became unconscious, had a further fall in blood-pressure, and soon showed signs of shock Fortunately, laying the patients flat and applying restorative measures resulted in obvious improvement

Until recovery-rooms with trained staff are as standard in the theatre equipment as operating-tables and anæsthetic machines, such incidents are certain to recur Meanwhile it is of vital importance that postoperative hypotension should be recognised and that doctors and nurses should be aware of its inherent dangers

Glasgow

WOOLFRED SNIPER

PILONIDAL SINUS OF THE UMBILICUS

SIR,—With reference to the article by Dr Sadeghi-Nejad and Mr Rains (March 15), it may be of interest to report a similar case

A hirsute Italian man aged 34 came to see me recently complaining of a sore navel Examination revealed a similar picture to the illustration shown, a bundle of downward pointing hairs with roots orientated inwards, protruding from the umbilicus, in which there was some moist intertrigo The umbilicus was held open with forceps and the bundle was withdrawn Most of the hairs were free, but the root ends of a few were embedded in a small mass of granulation tissue lying at the bottom of the pit The granulations were touched with silver nitrate and the soreness subsequently subsided

I referred him to Mr Gordon Bohn who found a few more loose hairs at the bottom of the umbilicus and agreed that no further treatment seemed necessary

Obituary

DANIEL ALEXANDER DAVIES

B Sc Wales, F R C S

COMBINING general practice with surgery in a way which has now become difficult, Alec Davies, of Walmer, was a man who brought warmth and vigour into all he did His strong surgical leaning found expression in his work at the Victoria Hospital, Deal, but he was essentially a good all-round doctor, whose therapeutic ability came largely of liking people and taking much trouble to help them

Entering St Thomas's Hospital in 1920 with a B SC from Wales, he qualified in 1922 and later became resident-anæsthetist at the hospital Soon after taking his F R C S in 1926 he settled in Deal, where he quickly built up a reputation by his high standards of practice Over the years he came to number among his patients several eminent colleagues, and their confidence in him was a tribute to his medical skill and his honesty of purpose

In the 1914-18 war he had served in the Welsh Guards (in which he always retained great pride and interest), and in the second war, though aching to serve abroad, he managed to relieve his feelings by combatant training of the local Home Guard Though there was, in the end, no invasion, there was also war surgery to be done in Deal The bombing and shelling of the early days and the damage done to his home perturbed him not at all, but merely increased the trenchancy of his remarks about the enemy and all their works

Soon after the war Davies had the first, and almost fatal, attack of coronary thrombosis which he described so vividly in our Disabilities series His method of managing it was the then unusual one of ignoring symptoms and returning at the earliest possible moment to full work Nor did he confine his interests and activity to his practice The St John Ambulance Corps, the Royal Cinque Ports and Sandwich Golf Clubs, the Betteshanger Rugby Football Club all enjoyed his constant support He kept up a close attachment with St Thomas's Hospital and had lately been elected a representative of St Thomas's on the United Hospitals Club He also found time to serve on the Kent and Canterbury executive council and on the South East Kent hospital management committee

The following tributes show something of his quality as a man and his skill as a doctor H L writes

Alec Davies was an able man, practical and gifted with a large fund of common sense, a clever diagnostician, and a general-practitioner surgeon of the first rank Kindness and sympathy he gave readily to anyone who was in real distress, but he spent little time on malingerers, he hated humbug and any action he thought not straight He was progressive and kept his knowledge up to date not only by the study of journals and modern textbooks, but by frequent visits to his old hospital where he attended the wards, operating-theatres, and occasional lectures One could not fail to be impressed by the way in which he tenaciously clung to what was good in the clinical teaching of the days when he was a student and on the house During his visits to St Thomas's he enjoyed meeting students, asking them questions, ragging them, and giving them tips that would be useful to them when they were in practice On looking back, one feels that if he had had the opportunity he would have been a very sound and popular teacher

J S H, who worked with him for many years, describes him as a general-practitioner specialist who was "as much at home as a family doctor in a miner's house as in the operating-theatre of his local hospital"

We shall always remember Alec Davies (he continues) for his disarming forthrightness of speech, irrespective of the company in which he found himself His comments on any trying situation were invariably direct and colourful, but a gift of humour in his forceful expressions robbed them of offence, as indeed did the friendly charm and interest he bestowed on all who knew him One could always rely on him for an amusing story, carefully graded to the company in which he found himself, yet in his private life he was of a serious disposition, and technical reading, especially of articles on modern surgery, was perhaps his main occupation at home He was a careful diagnostician, and many resident medical officers at the local hospital will have been edified by his practice in waving away X-ray films and reports until his thorough clinical examination of a surgical case had been concluded Both Deal and the hospital service will miss the help of an experienced practitioner who combined the skills of general practice with the outlook of a highly qualified consultant surgeon

Another friend recalls Alec Davies' talents as a writer and a reader

He had the ability to make written words come alive, as though he were talking He had wit and eloquence which, if disciplined, could have made him a notable writer, as he was a notable person Once or twice—his language a little tempered—he published his current opinions on the National Health Service, and for some months he had been incubating what he called his second Bevan lecture on the subject Though never one of those controversialists who go out of their way to do justice to the other side, he could always be relied on to say something wise, as well as something enjoyably wild His pleasure in writing went with a love of books, and he was an ardent reader both of general and professional literature

He died in Deal Hospital on April 8, at the age of 60, and leaves two daughters

WILLIAM HALLIBURTON McMULLEN

O B E, M B Lond, F R C S

Mr McMullen, consulting ophthalmic surgeon to Charing Cross Hospital, London, died on April 15 at the age of 81

His father was a doctor in Camberwell, and he was educated at the City of London School and King's College He qualified from King's College Hospital in 1898, and after holding house-appointments at King's he took the F R C S in 1901 After holding the posts of curator and pathologist at the Royal Westminster Ophthalmic Hospital (now part of Charing Cross Hospital) he was appointed assistant surgeon to that hospital Later he also joined the staffs of the Miller General Hospital, The Hospital for Sick Children, Great Ormond Street, and the Royal Northern Hospital During the 1914–18 war he was ophthalmic specialist to the Central London recruiting depot After he retired from his hospital appointments he remained a helpful and valued member of the house committee of the Royal Westminster Ophthalmic Hospital

He married in 1906 Miss Kate Higgins who survives him with three sons

M L H, who was one of Mr McMullen's clinical clerks, writes

Even in 1912 he was white-haired and of distinguished appearance He was a good teacher and extremely thorough in his approach to every case, even in a busy clinic This opinion I was able to confirm when I followed him as ophthalmic surgeon at the Miller Hospital, and saw many of his old notes and cases When, in 1934, I once again followed him, this time at Charing Cross Hospital, I was able to see how much his opinion on medical cases had been respected It was largely through his inspiration and planning that we were able, in 1930, to open our present hospital in High Holborn, with its 100 beds in place of the 40 beds of the old hospital Besides being a careful diagnostician he was a good and meticulous operator and very light-handed Even in illness he preserved the calm and unruffled exterior which was so characteristic of him

A memorial service will be held at 11 A M on Wednesday, May 7, at St John's Wood Chapel, London, N W 8

PAUL OSWALD WOLFF

Dr Med, Dr Phil Berlin

BEFORE he left Germany in the '30s, Professor Wolff had won a national reputation as a pharmacologist, as a university teacher, and as a medical editor He used his years of exile to win an international reputation as an expert on the problems of drug addiction and as a sectional chief of the World Health Organisation

He was born in 1894 in Berlin, the son of Geheim Sanitatsrat Dr Alfred Wolff, and studied medicine in Göttingen, Freiburg, Greifswald, and Berlin His career was interrupted by the war, in which he served in the German army and was disabled by gas, and he did not qualify till 1919 After taking his doctorates in medicine and in philosophy he joined the department of pharmacology in the University of Berlin, and became a Privat Dozent In 1925 he joined the editorial staff of the *Deutsche Medizinische Wochenschrift* and in 1930 he became editor-in-chief During these years he was also an adviser on drugs and drug addiction to the German Ministries for home affairs and for health and he was for some years secretary to the German Arzneimittel Komission He took an important part in drafting the regulations for the use of opiates which were accepted at the meeting of German doctors held at Danzig in 1928 and which are still current practice in Germany today

In 1933 Wolff emigrated to Switzerland where he became a regular contributor to the *Schweizerische Medizinische Wochenschrift* He also wrote several reports on narcotics for the League of Nations He was well fitted for this work by his mastery of English, Spanish, and French In 1939 he was sent to the Argentine on a mission for the League of Nations and he remained there till 1948, continuing his work for the League and also acting as an adviser to the Argentine Government In 1949 he returned to Geneva on his appointment as chief of the Addiction-producing Drugs Section of the World Health Organisation After he retired in 1954 he continued to lecture and write on the control of narcotics and in 1956 he visited this country to speak at a meeting of the Society for the Study of Addiction (of which he was a vice-president) His paper on heroin from the international point of view was later published in our columns Last year he was made an honorary professor of the Free University of Berlin

A man of high intelligence, a scholar, and a collector of works of art, Wolff was also an engaging companion, of deprecating humour Latterly frail, he made little concession to physical disability He was, as a friend says, "a man who never gave up", and to the day of his death, in November of last year, he was busy on his study of synthetic narcotic drugs

Notes and News

MEDICAL RESEARCH COUNCIL

A GROUP for research on the chemical pathology of steroids is to be established in Sheffield, under the direction of Dr J. K. Norymberski. The group will study steroids in relation to disordered metabolism in disease in general, not only in rheumatoid arthritis. The board of governors of the United Sheffield Hospitals, which is associated with the Council in establishing this group, is to provide accommodation at the Jessop Hospital for Women and to meet a third of the running costs; the board has received grants, of £4000 each, from the British Empire Cancer Campaign and the Sheffield and District Convalescent and Hospital Services Council, to meet capital costs.

The Council's obstetric medicine research unit, under the direction of Prof. Dugald Baird, is moving into new accommodation—an additional storey on the antenatal wing of the Aberdeen Maternity Hospital. The building costs are to be met by a grant of £60,000 from the Scottish Hospitals Endowment Research Trust, and the equipment and nurses will be provided by the North Eastern Regional Hospital Board (Scotland). There will be eight beds, besides laboratories and offices for the social research section, which should make possible intimate collaboration between clinicians and research workers. The work of the unit began during the late war with studies of perinatal mortality, which showed the significance of maternal nutrition; later studies showed the importance of the mother's physique, health, and social background. More information is sought on the social background of normal pregnancy, and on the biochemical changes during pregnancy (particularly in the sex hormones) and their relation to physiological efficiency in pregnancy and labour.

MINISTER'S REPLY TO SELECT COMMITTEE ON ESTIMATES

IN their report on the running costs of hospitals, the select committee on estimates made some pointed criticisms of the Ministry of Health, which have drawn an equally sharp reply from the Minister.[1] The committee said that it was clear to them that "if full value is to be obtained for the large sums of public money that are spent every year, there must be more time and attention devoted to long-term planning", and they expressed depression at "the apparent lack of vigour with which some fundamental problems are being faced by the Ministry".

The Minister dissents from the suggestion of lack of vigour, and asserts the opposite. As evidence he cites matters specifically mentioned by the committee that have already been the subject of action. Thus the committee made recommendations about the appointment and assessment of salaries of hospital administrators; both these recommendations, says the Minister, have been made by Sir Noel Hall in a recent report, which is being considered. The committee recommend the fullest use of departmental costing; the Minister agrees, and has already informed hospital authorities of the importance he attaches to it. In the past, costing returns have been taken into account in deciding allocations for developments; in future the more accurate information from departmental costing will be used. The committee urge that medical students should be required to know about the financial structure of the health service and the cost of treatments. The Minister points out that the chief medical officer of the Ministry has at intervals provided information to medical schools about prescribing costs and asked them to include it in the curriculum; a committee is at present considering the factors in the cost of prescribing. There has been a considerable increase in joint contracting, which is recommended by the committee. The committee also called for an inquiry into the domiciliary consultative service, and for a relaxation of the definition of capital to finance small revenue-saving projects out of savings in running costs; the Minister will institute the inquiries and consider the redefinition.

TEN YEARS OF THE SLOUGH INDUSTRIAL HEALTH SERVICE

IN Slough many factories are concentrated in a small area, in and near the Trading Estate; thus it lends itself to the type of cooperative industrial health service that was set up there in 1947.[1] The latest annual report surveys the first ten years' running of the service.[2]

When the Slough Industrial Health Service began there were 52 member firms, with a total of 6324 employees; now there are 179 firms, with 17,748 employees. The care of all the 11,500 employees of member firms that have no medical department of their own costs about £2 a head yearly; half of this is accounted for by the casualty service, which treats over 500 patients a day, 98% of whom continue at work after treatment; only 0·8% of new patients attending the general clinics have to be referred to hospital. There are consultants (an orthopædic surgeon, a plastic surgeon in charge of the hand clinic, and a cardiologist), who hold regular clinics, besides several full-time doctors on the staff experienced in industrial medicine and dermatology. In addition to the central and two peripheral clinics, there is a mobile dressing-station which visits the more distant factories and prevents much loss of time. About 12% of the patients attending the general clinics have eye injuries.

The clinics are supported by X-ray, pathology, and physiotherapy departments, and there is a social-service worker. Patients who need intensive reablement are treated (as inpatients or outpatients) at Farnham Park centre, which also attracts patients from hospitals in London and elsewhere; its cost, previously shared by the Service and the Regional Hospital Board, is now borne entirely by the Board. Besides all its remedial work, the Service provides an occupational hygiene service, headed by a physician, an engineer, and a chemist, which is equipped with chemical and dust laboratories and a workshop. This service, controlled jointly with the London School of Hygiene and Tropical Medicine, advises on, and investigates, environmental conditions in the factories of member firms and occasionally others. Finally, many manufacturers require their workers to have initial or periodic examinations, and these, as well as annual examinations of senior executives of certain firms, are carried out by the staff of the Service.

RELEASE BINDINGS ON SKIS

THE ski accident prevention committee of the Ski Club of Great Britain has expressed concern at "the apathy and even antagonism" of some skiers towards the use of release bindings. The committee sought to investigate 180 ski-ing accidents on which claims were paid by one insurance company in 1956–57.

A questionary was sent to each of the 180 people concerned, of whom 148 replied. Of these 148, 59 had used some form of release binding. Of these 59, 27 sustained injuries unrelated to their release binding (e.g., collisions). Of the remaining 32, 15 admitted that their bindings had been improperly adjusted, in 10 further cases the release had operated and only a minor accident (e.g., sprain) resulted, and in only 2 of the other 7 cases were the skiers fully protected by both forward and rotational release bindings.

In no instance, says the committee, did the wearer of a release binding directly blame it in any way for the accident. The committee found that the proportion of skiers wearing release bindings rose steadily from 1·6% in first-season skiers to 54·5% in sixth-season skiers. "It is obvious that the more experienced skier realises the value of release bindings."

CLOSURE OF HOSPITALS

WITH the passage of time, developments in medicine and changes in local circumstances will probably lead to more readjustments in the hospital service if the community is to be served efficiently and economically, and the *Minister of Health* does not wish to discourage hospital boards from closing hospitals or changing their use where this may seem desirable He has, however, the responsibility of safeguarding as far as practicable the original objects of a hospital, and he has now sent a leaflet to hospital boards (H M [58]29) asking them to consult him before any change and describing the procedure to be followed

University of Glasgow

On June 18 the honorary degree of LL D will be conferred on Dr J Cruickshank, formerly professor of bacteriology in the University of Aberdeen, Dr T F Fox, editor of *The Lancet*, Dr E Husfeldt, professor of clinical surgery, University of Copenhagen, and Sir Hans Krebs, professor of biochemistry, University of Oxford

Royal College of Surgeons of England

At a meeting of the council on April 17, with Sir James Paterson Ross, the president, in the chair, Mr T Keith Lyle was elected a member of the Court of Examiners Prof R B Kerr and Prof E J Wayne were appointed Sir Arthur Sims Commonwealth travelling professors

It was agreed to establish a Court of *Anæsthesia* in the College

The following were elected fellows of the college without examination as being medical practitioners of 20 years' standing

Prof R W Scarff, Air Vice-Marshal John Conrad Neely, Mr George Bell, Mr G H Thomas, Prof F C Wilkinson, Prof A E Galloway

The Jacksonian prize for 1957 was awarded to Mr B B Milstein The council selected the subject for the prize for 1959 non-specific granulomata of the alimentary tract Mr P C Williams and Dr F C Chesterman were appointed Imperial Cancer Research Fund lecturers for 1958

Diplomas of fellowship were granted to P M Marnie and M F Sturridge

The following diplomas were granted, jointly with the Royal College of Physicians

D L O—A D Soysa

D O—A P Barclay, B J Bowden, B D Coote, C C Ewing, T P Griffith, W M Higginbottom, Elizabeth D Jamie, R V Kotnis, C G McEwen, I A Mackie, N L L Margetson, I A Mir G A I Namsoo, Margaret C W Neilson, J B Parton, Than Pe C O Quarcoopome, Dev Raj T V Ranganathan, A P Sah L F Shanahan Froma Somerville, Peter Taylor D O Tonkin, Ursula Walters

D T M & H—A J Berman T K Bose, J K Chakravartı, D D E W de Alwis Ugo Fornari M C Gupta, Maswoodul Haque, H T Heah, M D Heyman, F N C Ho, M H Husaini, R T Jensen P V Krishnamurti Leif Langlo, G R L Lyons W R McKibben P D Marsden, R J Onyango I S Pillay, Nargis N J Rana, B N Roy Louis Saint-Arnaud M Y Siddiqui J P Soonawalla Subramaniam Thanikasalam M McC Wilson C M Wylie

D Phys Med—A M Bain, J D K Palmer

On Tuesday, May 6, at 5 P M at the college, Lincoln's Inn Fields, W C 2, Dr H Rocke Robertson, professor of surgery in the University of British Columbia, will give the Moynihan lecture, on observations on wound infection

Social Security Agreement between United Kingdom *and France*

A revised convention on social security between the United Kingdom and France will come into force on May 1

The convention consolidates and replaces the provisions of the existing agreements It covers benefits for sickness, maternity, industrial injury old age, widowhood, and death, it extends French old age allowances to United Kingdom nationals, and it ensures that medical benefits under the French insurance scheme available under the earlier arrangements only to the families of United Kingdom nationals insured under that scheme may now be extended to British retirement and industrial injury pensioners and to persons receiving long term sickness benefit

Australian National University

Dr F C Courtice has been appointed to the new chair of experimental pathology in the John Curtin School of Medical Research at Canberra

Royal Anthropological Institute of Great Britain and Ireland

On Thursday, May 15, at 5 30 P M at the Institute, 21, Bedford Square, London, W C 1, Dr Raymond Cabannes, director of laboratories, *Faculty of Medicine, Algiers, will* lecture on the distribution of abnormal hæmoglobins in Algeria, Hoggar, and High Volta

Problems of Old Age

Mr Derek Walker-Smith, the Minister of Health, when he addressed the Conference of the National Old People's Welfare Council in London on April 17, discussed the pattern and underlying principle of what services for the old should be He reiterated that the best place for old people was in their own homes, with help from the home services if need be, but he pointed out that, however successfully this principle was applied, the time must come when the struggle to maintain independence becomes too great a burden for many old people to sustain with any satisfaction to themselves "The problem then arises," he added, "of knowing when this point is reached, just when the emphasis should be switched from helping people to stay independent, to encouraging them to feel that they might now find greater comfort and peace of mind in sharing life in a community with others in whom the means for self-reliance is running down" There was need for further investigation of these problems, and for that reason he welcomed the further grant offered by the Nuffield Foundation for a detailed factual study of the reasons why people enter *homes for the old*

Surgeon Rear-Admiral W R S Panckridge, R N, has been appointed an *honorary* physician to the *Queen in succession to* Surgeon Rear-Admiral David Duncan

Prof R B Hunter has received a Purdue Frederick Medical Achievement Award The award was announced by the International Council for Health and Travel

On April 21 the Freedom of Wolverhampton was conferred on Dr J H Sheldon, who has been a citizen of the borough for 37 years and is now senior physician at the Royal Hospital, Wolverhampton

Dr W T M Gilbert has been appointed an official member of the executive council of St Helena

At a public meeting to be held by the London Marriage Guidance Council on Thursday, May 8, at 8 P M, at County Hall, Westminster Bridge, S E 1, Dr Alfred Torrie will speak on the place of marriage counselling in the work of the family doctor

The Association of Medical Records Officers will hold an educational conference and exhibition from May 14 to 17 at the Sun Pavilion, Harrogate The speakers will include Dr W P D Logan, Dr W G Daynes, Dr J L Cates, Mr A W Purdie, and Dr C A Holman Further particulars may be had from Mr A L J Turner, the secretary of the association, United Bristol Hospitals, Royal Infirmary, Bristol, 2

This year for the first time the German Academic Exchange Service is offering a number of grants to young doctors who wish to visit German university institutes and clinics The grants (125 DM a month) are tenable from Oct 1, 1958, for twelve months or less Further particulars may be had from the London branch of the service, 43, Parliament Street, S W 1

CORRIGENDA *A Chair of Pædiatric Surgery*—In last week's annotation (p 839) we asserted that the new chair at the Institute of Child Health in the University of London was the second of its sort A correspondent informs us that such chairs are not uncommon in the U S S R

Control of Treatment in Myxœdema by Electrocardiography—In our issue of Jan 18 there were two errors in doses in the article by Dr P C Gibson On p 129 the dose in case 2 after 10 days should be gr 4½, not gr 1½, and on p 130 the maintenance dose in case 10 should be gr 1½, not gr ½

The Lancet · Saturday 3 May 1958

SOCIAL MEDICINE IN DEVELOPING COUNTRIES *

CICELY D WILLIAMS
B.A., D M Oxon, F R C.P, D T.M & H
FORMERLY ADVISER IN MATERNITY AND CHILD HEALTH, SOUTH EAST ASIA REGION, WORLD HEALTH ORGANISATION

(concluded from p 866)

Welfare and Health

SOCIAL medicine, as its name implies, does not function in a vacuum, and its exponents must consider other forms of social enterprise. During the last fifteen years experiments in social welfare and community development have been made in various forms in various countries There have been drives for literacy and mass education, sometimes based on what is known as "fundamental education" In many places clubs have been organised, both for men and for women, with the object of improving agriculture, diet, domestic and community living standards by encouragement of self-help Aid has been provided for the handicapped, the aged, and the neglected, for as old tribal structures break down there has to be some more sophisticated type of social security to take the place of traditional forms

Where these experiments have been organised in cooperation with the basic departments of law, health, education, and agriculture, and where they have promoted the teaching of home economics, they have helped medicosocial work But sometimes they have diverted attention from essentials to less essentials For instance, money has been spent on recreation halls when schools and clinics were lacking A campaign to build latrines has not taken into account the fact that their use and maintenance would need a change in habits which could only be achieved by gradual education In programmes of "health and welfare", the work of the medical department has not been expanded, and "welfare centres" have been launched though trained medical staff was insufficient

The indiscriminate use of the expression "child welfare" has sometimes hindered work in child health Thus "child welfare" centres, which were originally devised for countries where child-health services were already provided by hospitals and by doctors in general practice, are being set up in places where proper medical facilities do not exist It is rather as if the Good Samaritan had started by giving the victim money for his journey before picking him off the road and attending to his injuries

It might be thought that in countries where there is a high infant and child mortality almost any work for children is better than none But schemes for welfare have sometimes deferred the establishment of organised health centres and hospitals, and recruited staff which was even more urgently needed by the health services

Medicine has a long, arduous, and expensive training Nursing is traditionally overworked and underpaid. But "social work" is regarded as a less exacting profession, and it is often easier to recruit large numbers of social workers than one or two nurses The social services sometimes offer not only an easier training and better salaries, but also better working conditions and better transport facilities As a result there may be no pupils at an excellent training school for health nurses, while in the nearby "community development" training centre large numbers are preparing for "health and welfare"

In one place a new health and welfare project was started in an area where health was a major problem. It began by a complete house-to-house census Later a medical unit was set up; but, though it was well staffed and equipped, it was little used by the people It was then pointed out that the original census had been made not by the medical but by the social workers I believe that had the medical workers taken part in this initial stage of the work they would have made their contacts when the people were most receptive, and the centre would have got off to a better start. As it was the medical staff missed their opportunity, and, in the face of many and untouched health problems, there was relatively little that the "social workers" could do

Some countries where rapid changes are taking place have serious problems of neglected and delinquent children Their maternal and child health services are still rudimentary, doctors cannot give enough time to the clinics, and the hospital provision for sick children is inadequate The health visitors have too large areas to cover, and spend so much of their time in travelling, that they have little left for visiting or keeping in touch with non-cooperative parents The authorities in these countries are now being urged to spend more money on children's homes and children's officers If they could instead be induced to expand and improve their maternal and child health services, this not only would be more economical, but most of these social complications and disasters would be avoided and both physical and mental health would be improved

Where epidemics of preventable diseases monopolise the hospitals, doctors take steps to prevent these diseases Where hospitals are crowded with accidents, behaviour problems, gunshot and stab wounds, alcoholics, and the usual flotsam and jetsam of social tides and storms, the doctors' duty is not only to salvage but also to try to prevent Certainly social welfare and community development have a valuable part to play in health education, in adult education, and in organisation of voluntary work. They can do much to extend the social usefulness of the medical departments If doctors and nurses were better trained in the social functions of medicine, they would be able to cooperate more effectively in community development schemes

Strains of Adjustment

The sophisticated countries have their own peculiar health problems, such as cardiac emergencies, peptic ulcers, allergies, and dental caries These are all beginning to appear in the developing countries No less serious are the problems in mental health, including the angry adolescents of all ages, the suburban neurotics, and a variety of social misfits

In the primitive village, behaviour is remarkably standardised Health and survival may be uncertain, but discipline and a certain social security are assured Many sophisticated people lack the poise, reserve, and dignity conspicuous in some of the less sophisticated communities

As territories develop economic independence and achieve more responsibility for self-government, more posts become available for men and women with training and skills which are very different from those needed in the scattered farms or isolated villages of a previous era But education brings new stresses It may separate the child from his unlettered relatives He leaves a world of uniformity which does not demand decisions and where every experience is shared with the family and with the community, and enters a world which he cannot share with his fellows He is confronted with enlarged possibilities but with the embarrassment of choice Too often he develops what is now called "cross-cultural shock"

---

* Abridged from the Milroy lectures for 1958, delivered before the Royal College of Physicians of London on Feb 4 and 6

The education demanded or offered conforms to the orthodox European standards, leading to university qualifications Much of it is alien to some of the developing countries and this, too, produces a sort of unreality Of late, efforts have been made to modify curricula so as to make them more applicable to local conditions, but this is not always easy Though mechanical and scientific facts are the same all over the world, they are still strange to the primitive village

The permissiveness of modern education imposes an added strain on pupils accustomed to a stricter discipline

These stresses of education often show themselves in restlessness There is a tendency to flit from job to job, not only in search of higher wages but in order to explore as many openings as possible Often there is difficulty in achieving any sort of self-criticism

But even those who are not exposed to the strains of education have to adjust themselves to an unfamiliar monetary system, to town life, to regular work, to altered food habits, to commercial pressures, and to the relaxation of traditional authority Inevitably new disciplines and responsibilities impose a considerable strain, and it is not uncommon to find disorderly behaviour among workers who have found a new freedom and a new wealth but have failed to accept new sanctions Students in schools and colleges, and men and women in responsible posts may likewise prove unable to bear these stresses Cases of hysteria, schizophrenia, and other disorders are not uncommon Some recover, but others cannot use their enlarged opportunities In some areas the Christian missions have done much to provide stability and standards of conduct in a changing world In many of the mission hospitals equipment may be of a poor standard, yet the social medicine and the educational services are excellent

The indices of health are not only rates of mortality and morbidity but also the incidence of violence, crime, alcoholism, delinquency, and inadequacy If the medical services in developing countries were more aware of their social functions, they would become more respected as instruments of social policy

Assessment of Needs

Vital Statistics

The advanced countries can turn to vital statistics and records from the hospitals and medical services for guidance on their policy But in many of the developing countries vital statistics do not exist or are quite inaccurate, while hospital and other records may be both unrepresentative and unreliable

Where major epidemic diseases are prevalent, it is obvious, without waiting for any statistical analysis, that these must be combated The next stage is reached when endemic diseases, such as malaria, yaws, and schistosomiasis, loom large These diseases can be diagnosed either by inspection or by fairly simple microscopy Their incidence can be assessed by surveys, and there has been a tendency to permit the prevalence or absence of these diseases to obscure other parts of the health picture

For instance, the municipality of Singapore in the years 1935–40 was free from smallpox, cholera, and plague Malaria was well controlled and yaws and filariasis almost unknown It was therefore described in the reports as "healthy", or "remarkably healthy", though beriberi and tuberculosis were common, while the infant-mortality rate was over 150

In the absence of vital statistics, some information may be gathered from census figures, from sample areas, or from analogous conditions where statistics are available

The infant mortality is generally a fair index of the health of a community But the following figures from communities at three stages of development show that the disadvantages of bad conditions bear most heavily on children between the ages of 1 and 5

	Death rate	*Birth-rate*	*Infant mortality*	*Mortality in 2nd to 5th years*
England 1955	10	15	25	0 9
Jamaica 1948	13	31	86	13
Egypt 1947	22	38	205	49

Thus in Egypt in 1947 the total death-rate was only about twice that of this country in 1955, the infant mortality was eight times as high, but the toddler mortality was no less than fifty times higher It is the 1–4 age-group that is the most sensitive index

The contrast between the different countries can be expressed in a different way For instance, in Sweden less than 5% of the total deaths take place under the age of 5 years In Malaya, over 40% of the deaths are in the under 5's, and in Mexico nearly 50%

Records in villages in the Gambia and Tanganyika gives infant-mortality rates of 308 and 420 respectively From these we can get some idea of the enormous wastage of child life which is going on

It is impossible to overestimate the importance of this wastage In my experience it has a profound effect on the lives of the people A high child mortality creates severe stresses—physical, emotional, and economic It breeds fatalism and apathy In the overpopulated countries it is a most tragic and expensive method of population control

Surveys

In areas where vital statistics are not available, attempts have been made to assess health by surveys These have sometimes proved useful, but they can be misleading unless great care is taken to ensure that standards of comparison are valid

A survey is commonly conducted by a specialist in one branch of medicine or in one particular disease He may be well qualified to identify every case of leprosy, or trypanosomiasis, or eye disease, or schistosomiasis, but he is often unable to assess the importance of his specialty in the total health picture

In a survey the mathematical chances of meeting a chronic disease are, of course, very much greater than those of meeting an acute one In malaria, the blood may show parasites for many years, with leprosy or blindness people may survive 40 or 50 years, and diseases such as these may be recognised unfailingly But there is relatively little chance of seeing the diseases that mainly affect the children Gastro-enteritis may kill in a few days, respiratory diseases and acute beriberi may kill in a few hours t is often said that malaria is the agent chiefly respon- le for a high infant mortality, but it is hard to say ether the cause is not malaria plus malnutrition, which itself may be due to dyspepsia or recurrent enteritis ropean medicine has learnt to shun the double diag- sis, but in developing countries doctors must be pared to find a great complexity of diseases The exact nposition may show geographical and seasonal varia- ns, but it is not rare for children to have five or six ferent diseases at the same time A typical combination uld be malaria, ascariasis, beriberi, rickets, bronchitis, d scabies

Most surveys are ill equipped to observe the genesis d development of disease and very few have been nducted by pædiatricians Some depend on assembling e population in groups for inspection—when, in my perience, sick children are often left at home Though survey may give an idea of the extent to which mal- trition exists, it will seldom throw much light on the uses

Surveys by anthropologists and by social anthropolo- sts sometimes lead to constructive suggestions, but metimes merely to further surveys They are liable to ncentrate on one aspect of the problem It used to be ithropological measurement, more recently it has been e dream life or the sex life, the initiation rites, the other-child relationship, or the kinship pattern They ldom pay much attention to the part played by ill alth, or by menaces to health in determining human haviour If repeated surveys are carried out, and pecially if they are not followed by constructive action, ey may produce a sort of allergy and a non-cooperative mmunity In fact, surveys should not be lightly under- ken Much time and money can be wasted that would ave been better spent on improving permanent medical cilities for treatment and for observation

ecords and Histories

Sometimes useful information can be gathered from ospital or dispensary figures But these, again, must be reated with caution In one area it was found that only % of the deaths in hospital were in children under years of age, and yet in that area, half the total deaths vere in the under-5s Some hospitals do not give the age f the patients in their registers, so that without going hrough individual case-sheets one cannot find how many re children

Some observers have tried to collect information from ersonal histories, but these, too, can be misleading In ome areas women are anxious to prove their fertility nd will claim to have had more pregnancies than they have actually achieved In others the parents are unwilling to discuss the numbers of their children, for “ if we count them today, tomorrow they may die ” Again, others simply forget

In fact there is no short cut to assessment of status, needs, or resources Only by gaining the confidence of a people is it possible to discover either the facts or the attitudes and potentialities Even in countries where statistics are available their value must ultimately depend on the observer His experience, his powers of observation, and his diligence are the deciding factors in any form of assessment Many aspects of health cannot be expressed statistically But they cannot therefore be ignored

A Neglected Specialty

The primitive community depends on children for wealth and for survival More children mean a bigger, stronger tribe, more hunters, more field workers, more security for old age The primitive community also accepts as inevitable that perhaps half its children will die before maturity Nearly everywhere, except in certain overcrowded urban conditions, babies are welcomed with joy—but with little confidence

Medical departments have achieved spectacular success in controlling diseases, but improvements in the standard of living and of education have not kept pace, and too often child care has been neglected Disease control campaigns have led to a fall in the death-rates, but the birth-rates remain high, and a too rapid increase in population may jeopardise progress

Yet the countries, such as New Zealand, Scandinavia, and the United Kingdoms, which have the highest standards of child care and health, are not countries with high birth-rates It is only when people learn to have confidence in the survival of their children and pride in their future, that they begin to see the desirability of limiting their families to the number they can expect to look after properly

Efforts are being made in some places to encourage family planning But this cannot be forced upon a reluctant population even by the most totalitarian regime It must come as the result of improved parental responsibility It is through the maternal and child health services that responsibility can be encouraged and that birth-control techniques may be taught

In 1553 Sir Thomas Phaire[4] listed the diseases by which “ most commonly the tender age of chyldren is chiefly vexed and grued ” His forty-odd headings included·

> Stiffness of the limmes, watrying eyes, scabbynesse and ytche, canker of the mouth, streytnesse of the wynde, feblenesse of the stomake and vomiting, colyke and rumblyne of the guttes, fluxe of the belly, wormes, failynge of the skynne, chafyng of the skynne, leanenesse, lyse

The conditions among children in the developing countries today are better described in his book than they are in some books on tropical medicine, which sometimes give more attention to counting the hairs on the head of the mosquito, and the contours of the œsophagus of the larval nematode than to the disorders prevalent among the children

In many of the developing countries maternal mortality is high Early marriage, repeated pregnancies, and perhaps extensive female circumcision may lead to abnormalities and complications Sometimes these are due not so much to neglected obstetrics as to anæmia, malnutrition, malaria, and helminths In many areas women bear the burden of agricultural and laborious domestic work They may habitually carry heavy loads at every stage of pregnancy and of lactation As yet the effect of physical overwork on the incidence of premature labour, hæmorrhages, ruptured uterus, and failure of lactation has been insufficiently studied in fact the social aspects of midwifery need more attention But much is being done Maternity work is popular, obstetricians are often appointed, and in many countries there has been rapid progress in the training of midwives

The position as regards child health is much less satisfactory

In many of the developing countries there is little or no specialist care for children in wards or outpatient departments There is nobody to teach, advise, or supervise child care Even if international or other funds are available for treatment or research, there is no pædiatrician to devise suitable programmes

---

[4] Phaire T Boke of Chyldren (Edited by A V Neale and H R E Wallis Edinburgh, 1955)

If a doctor is recruited who happens to have a special interest or qualifications in pædiatrics, he may not be given appropriate recognition, and may turn his attention to some subject offering better prospects As there is no hope of building up a special department, there is no continuity of staff Without continuity, research is restricted, records are poorly kept, follow-up is neglected, and progress is impossible

Some sections of reports on maternal and child welfare make no reference whatever to children Some mention that most of the children attending "well baby clinics" are in fact sick, but give no information about any treatment provided Hospital records rarely give the ages of patients, and even where there are children's wards there may be no cooperation between them and the welfare centres, and no follow-up

Welfare clinics may be under the jurisdiction of a medical officer of health who has little experience in pædiatrics and none in tropical pædiatrics Health visitors trained in Europe may know little of the conditions or the diseases of the area to which they are appointed Sometimes, being imbued with the idea that they should do preventive and not curative work, they turn away sick children or refer them to some medical assistant with little or no pædiatric experience Again, the welfare centres may refuse attention to children over the age of 18 months or 2 years, though the 1–4 age-group is known to be in great need of help Sometimes the health visitors are kept busy with maternity cases, or are given so little transport that they have small opportunity to visit in the homes

These are serious defects in the organisation of child health work There are places however where magnificent work has been done In the rural areas of Singapore Island the infant mortality was reduced from 267 to 90 in eleven years by a most efficient and appropriate maternal and child health organisation In Ilesha in Nigeria and in Vellore and other places in India the idea is being introduced that the children's clinics should be conducted from, and in close association with the children's departments in a hospital If such integration is more widely acccepted, it will lead to great improvement in child health, in nutrition, and in the standard of living Success will depend on the calibre of the pædiatrician and perhaps even more on the continuity of his appointment

The pædiatrician who goes to a developing country will find that he must be adaptable The type of work to which he has been trained in a more sophisticated region may have done little to prepare him for his new responsibilities

He will have to acquire a great deal of local knowledge of the position and work of women, attitudes towards the child, local traditions, food habits, and resources

He will find that instead of dealing with a few rare diseases, he soon has his clinics and his wards overcrowded with large numbers of very common diseases There is the problem of the multiple diagnosis, when the whole spectrum of disease may be new to him Necropsies may be difficult to obtain and laboratory equipment rudimentary

Few or none of the patients arrive with a doctor's letter, and the histories offered by parents may be unhelpful To the question "What is wrong with the child?" the answer may well be "A witch looked at him" or "A thunderbolt fell on him" Even the age of the child may be unknown

The pædiatrician may find that his staff knows very little about child health He must spend a great deal of time training, and teaching nurses and other doctors, and in organising record-keeping and follow-up In addition he may have to spend much energy on informing his seniors and superiors

Conclusion

A maternal and child health programme should be concerned with the care of the child, the whole child, and everything to do with the child, including the family It should include school health It is obviously one of the finest instruments for social medicine

Though children under 15 and their mothers may between them comprise over 70% of the population, the maternal and child health service is often looked on as a minor detail in the public-health programme But, whereas public health is geared to provide impersonal services, maternal and child health is essentially a service to individuals

If maternal and child health clinics are organised and supervised by a hospital, so that prevention, treatment, and follow-up can be integrated, they are likely to be far more valuable This integration means the continuing care to families, through episodes of sickness and health, in their problems of nutrition and behaviour, and at various stages of sophistication In this way medicine can become sufficiently flexible to give adequate and appropriate care to people with rapidly changing needs

At present too little attention is paid to child health in developing countries Pædiatricians are not much concerned with the tropics, nor are the tropical experts much concerned with pædiatrics, if we are to judge by the time spent on these subjects in the respective institutes In the United Kingdom teaching centres for undergraduates, postgraduates, and auxiliary workers could well teach more about child health, both clinical and social, and especially about the problems of the developing countries More short refresher courses, both in Europe and within the countries themselves, would be useful In research programmes more emphasis should be placed on long-term observation and less on short-term surveys and on laboratory investigations

Western, or scientific, medicine has much to contribute to international progress But its contribution will depend on its appreciation of the social sciences as well as of the biophysical, and it is perhaps through the balanced expansion of the child health services that its most important contribution can be made

We are continually reminded that life is short and art is long Life is indeed desperately short in some parts of the world, but art is not yet nearly long enough

I should like to record my debt to Dr H M M Mackay and to the late Prof John Ryle for the help they have given me I am also grateful to many people in many countries with whom I have worked, and with whom I have watched and discussed these problems Most of all I am indebted to my patients who ensured that I should become inevitably and intimately concerned with their social as well as with their clinical affairs

> " We have now described this disease as seen from within and then again from outside We know now the origin, the progress, and the outcome of the infection, as also the symptoms by which its presence is detected British medical skill seldom goes beyond that point in its research Once a disease has been identified, named, described, and accounted for, the British are usually quite satisfied and ready to investigate the next problem that presents itself If asked about treatment they look surprised and suggest the use of penicillin preceded or followed by the extraction of all the patient's teeth It becomes clear at once that this is not an aspect of the subject that interests them"—Prof C Northcote Parkinson, *The Pursuit of Progress*, p 102, London, 1958

HALL FELLOW IN SURGERY

UNIVERSITY DEPARTMENT OF SURGERY, WESTERN INFIRMARY, GLASGOW

Most patients benefit from cholecystectomy, but symptoms continue or develop in 15–20% of patients after cholecystectomy for stones (Judd 1925, Weir and Snell 1935, Macdonald 1943, Mock 1953) Post-cholecystectomy symptoms are probably even commoner after cholecystectomy for non-calculus disease (Bettman and Lichtenstein 1937, Wilson et al 1936, Meyers et al 1939, Doubilet 1943) Erroneous diagnosis may lead to ill-advised operation (Gray and Sharpe 1944)

These unsatisfactory results have led to use of the term " post-cholecystectomy syndrome ", which seems to us unsuitable because in many cases symptoms precede cholecystectomy, and the symptoms are not constant enough to be regarded as a syndrome In some cases they are thought to be due to autonomic imbalance (" biliary dyskinesia "), and in others to cystic-duct remnants with inflammation or stone (Hicken et al 1947, Garlock and Hurwitt 1951) or neuromas arising from the original operation (Womack and Crider 1947, Troppoli and Cella 1953)

We have investigated the incidence and cause of post-cholecystectomy symptoms, and related these to the reasons for cholecystectomy

Investigation

Clinical Material

200 patients underwent cholecystectomy between January, 1950, and December, 1956, in one surgical unit in the Western Infirmary, Glasgow, none were operated on by either of us 141 were traced We could not contact the others, mainly owing to post-war population shifts, but examination of their records has shown no material difference from the group reported

The age at cholecystectomy varied from 20 to 79 (mean 57), 79% were aged 40–69 114 were women and 27 men

Plan of Investigation

The records were analysed, and 126 patients interviewed Each was asked for his view of the effect of the operation, and he was directly questioned about specific symptoms 15 other patients, who could not attend, answered the same questions by post The length of follow-up was over a year in all cases, over two years in 110, and over five years in 41 Those with significant symptoms were investigated

Results

Reasons for Cholecystectomy

134 patients (95%) had had definite severe pain before operation—either biliary colic or from acute cholecystitis

Of the 7 who had no pain, 2 had had intermittent jaundice, 3 had an incidental cholecystectomy at operation for pyloric stenosis or post-gastrectomy syndrome (case 17), and 2 had had flatulent dyspepsia with gallstones and a diseased gallbladder wall

At operation, the gallbladder was diseased in 106 (75%) cases, and contained gallstones in 129 (92%) It was never removed unless gallstones were present or the wall was obviously diseased In most cases both conditions were met The common bileduct was explored in 38 cases (27%), stones were found in 22

5 patients had secondary biliary-tract operations (table I)

Follow-up

The 141 patients have been divided into three groups

106 patients (75%) had been completely relieved of all preoperative symptoms

15 patients (11%) had been relieved of all pain, but on detailed questioning admitted to some symptom of biliary dyspepsia We felt that these were within the bounds of normal, indeed 4 considered themselves completely cured Since none suffered any disability, we considered these two groups together as 121 cases (86%) whose symptoms had been relieved by the operation

20 patients (14%) had significant symptoms after cholecystectomy

In 18 of the 20 patients with symptoms (table II), the cause was an extrabiliary lesion, most commonly peptic ulcer In only 2 cases (7 and 13) could symptoms be ascribed to the biliary tract

In cases 5–12 the presenting symptoms first appeared after cholecystectomy In only 2 cases (5 and 7) could the symptoms be attributed to the operation

Case 5 —A woman, aged 68, underwent cholecystectomy for biliary colic, dyspepsia, and jaundice Stones were found in the gallbladder, the common bileduct was not explored She was well for four years, then abdominal pain and vomiting began At laparotomy (since the follow-up interview) adhesions

TABLE I—SECONDARY OPERATIONS IN 5 CASES

Case no	Cholecystectomy		Time interval	Second operation			Result
	Preceding clinical features	Operative findings		Symptoms	Operative findings	Procedure	
1	Biliary colic, jaundice	50 pea sized stones in thick G B , dilated cystic duct, C B D normal	1½ yr	Rigors, jaundice, pain	C.B D dilated, no stones, no pancreatitis	Sphincterotomy	No symptoms after 7 yr
2	Biliary colic, no jaundice	One stone in distended G B , C.B D dilated, no stones in C.B D	9 mos	Rigors, jaundice, pain	C.B D 19 mm diameter no stones, ampullary stenosis	Sphincterotomy	No symptoms after 3½ yr
3	Slight jaundice, dyspepsia, pain, hepatomegaly	Chronically inflamed G B , C.B D dilated, no stones in C.B D , cirrhotic liver	10 days	None (postoperative cholangiogram suggestive of stone)	Inflammation head of pancreas	Nil	No symptoms after 3 yr
4	Biliary colic, dyspepsia, no jaundice	Single stone in thick inflamed G B , C.B.D not dilated	7 yr	Recurring jaundice	C.B D dilated, stone at lower end	Removal of stone	No symptoms after 1 yr
5	Biliary colic, dyspepsia, no jaundice	G B chronically inflamed with stones, C.B.D normal	4 yr	Attacks of epigastric colic and vomiting	Adhesions crossing pyloric antrum	Division of adhesions	Too early for assessment

C.B D , common bileduct, G B , gallbladder

TABLE II—ANALYSIS OF POST-CHOLECYSTECTOMY SYMPTOMS IN 20 PATIENTS

Case no	Sex	Age at cholecystectomy	Findings at cholecystectomy	Time interval after cholecystectomy (yr)	Cause of post cholecystectomy symptoms
					Presenting initially after cholecystectomy
5	F	68	Cholelithiasis	4	Post-cholecystectomy adhesions
6	F	30	Chronic cholecystitis, cholelithiasis	2	Gross obesity, chronic ill health
7	F	65	Thin gallbladder, multiple pigment stones	3	Pernicious anæmia, kinking of supraduodenal C.B D
8	F	54	Thin gallbladder, cholesterol solitaire	3	Diverticulitis
9	F	63	Chronic cholecystitis, cholelithiasis	1½	Post-hysterectomy pelvic discomfort
10	F	40	Cholelithiasis	1½	Migraine with bilious vomiting
11	F	54	Chronic cholecystitis, cholelithiasis, duodenal ulcer	3	Obesity, hypertension, angina, duodenal ulcer
12	M	61	Chronic cholecystitis, cholelithiasis	3½	Myocardial ischæmia, renal colic
					Continuing despite cholecystectomy
13	F	28	Acute cholecystitis, cholelithiasis, stones in C.B D	7	Probable stone in C B D
14	F	51	Chronic cholecystitis, cholelithiasis, hiatus hernia	5	Hiatus hernia
15	F	51	Thin gallbladder, cholelithiasis	3	Periodic vomiting of unknown origin
16	M	36	Subacute cholecystitis, cholelithiasis, duodenal ulcer	4	Duodenal ulcer
17	M	65	Thin gallbladder with one pigment stone, anterior Polya gastrectomy with efferent-loop adhesions	5	Post-gastrectomy efferent-loop syndrome
18	F	51	Cholelithiasis	5	Obesity, chronic nephritis
19	F	50	Acute cholecystitis, cholelithiasis	6	Psychogenic vomiting
20	M	52	Thin gallbladder, cholelithiasis, huge paraœsophageal hernia	4	Diaphragmatic hernia
21	F	42	Acute cholecystitis	2½	Duodenal ulcer
22	F	42	Cholelithiasis	3	Duodenal ulcer
23	F	54	Chronic cholecystitis, cholelithiasis, gastric ulcer	7	Gastric ulcer
24	F	62	Chronic cholecystitis, cholelithiasis	3½	Obesity, lumbodorsal osteoporosis

C B D, common bileduct

crossing the pyloric antrum were divided The biliary tree appeared normal Her symptoms have not recurred in the few weeks since operation

Case 7—A woman, aged 65, had a cholecystectomy for attacks of biliary colic and jaundice A thin gallbladder, with pigment stones, was removed, the common bileduct, which appeared normal, was not explored Severe addisonian anæmia developed, and responded to orthodox treatment She continued to complain of right hypochondrial pain Intravenous cholangiography showed a moderately dilated common bileduct (maximum diameter 15 mm), with no stone, but a kinking in the supraduodenal part of the duct—possibly caused by adhesions to the gallbladder bed

In cases 13–24 the term post-cholecystectomy syndrome is inapplicable because the symptoms were present before operation In some cases, cholecystectomy seems to have been justified since acute biliary symptoms were relieved In others, where cholecystectomy was done for symptomless gallstones, the original symptoms continued Only in case 13 were post-cholecystectomy symptoms referable to the biliary tract

Case 13—A woman, aged 28, had had severe pain with jaundice At cholecystectomy in 1950, acute cholecystitis with cholelithiasis was found, and one faceted stone and some mud were removed from the common bileduct Seven years after operation she has recurring attacks of upper abdominal and back pain with associated nausea, jaundice, and biliousness There is probably a stone in the common bileduct Intravenous cholangiography has shown a moderately dilated duct (maximum diameter 13 mm two years ago, 17 mm now) and suggests obstruction at the lower end of the duct

Extrabiliary Causes for Post-cholecystectomy Symptoms

Peptic ulcer—In 5 of the 20 patients, post-cholecystectomy symptoms were found to be due to peptic ulcer

At the primary cholecystectomy, gastrojejunostomy was done on 6 occasions for associated pyloric stenosis Symptoms of ulceration continued only in case 11 Cases 16, 21, and 23 had typical ulcer symptoms for a long period before operation, and they have returned

In case 17 the cholecystectomy, done during an operation for postgastrectomy symptoms, had no effect on them

Symptoms due to peptic ulcer can be very easily confused with those due to gallstones Peptic ulcer has been found in 5% (Bruce 1926), 11% (Meyers et al 1939), and 8·5% (present series) of patients submitted to cholecystectomy

Diaphragmatic hernia—In case 14, acute biliary symptoms were relieved by operation but symptoms of hiatus hernia continued Case 20 had a cholecystectomy and repair of a huge para-œsophageal hernia, this unfortunately recurred, as did mild symptoms identical with those present before operation The biliary symptoms did not recur

Other causes—Many patients were obese, and in 4 cases their symptoms were clearly due to such associated conditions as angina (table II)

Cases 15 and 19 had intermittent vomiting of obscure origin No organic cause has been found, and there is evidence that it is psychogenic in both cases

Post-cholecystectomy Symptoms Arising in the Biliary Tract or Directly due to Cholecystectomy

7 patients (5%) have had postoperative symptoms due

TABLE III—RELATION OF PREOPERATIVE SYMPTOMS AND FINDINGS AT OPERATION TO POST-CHOLECYSTECTOMY SYMPTOMS

Results	Preoperative symptoms			Findings at operation				
	Pain		Jaundice	State of gallbladder *			State of common bileduct	
	Present	Absent		Diseased wall and calculi	Diseased wall and no calculi	Normal wall and calculi	Dilated	Stones present
No symptoms (106 cases)	102	4	30	79	9	18	28	19
Minor dyspepsia only relief of acute biliary symptoms (15 cases)	11	1	2	13	0	2	2	2
Significant post-cholecystectomy symptoms (20 cases)								
(a) Extrabiliary (18 cases)	16	2	2	10*	1	6*	0	0
(b) Biliary (2 cases)	2	0	2	1	0	1	1	1
Total (141 cases)	134	7	36	103	10	27	31	22

* In 1 case with significant post-cholecystectomy symptoms due to extrabiliary causes the state of the wall was not recorded though there was a calculus

to either associated biliary-tract lesions or the operation In 4 patients the symptoms were relieved by a second operation (table I)

Stenosis of the sphincter of Oddi —Cases 1 and 2 had had successful transduodenal sphincterotomy for stenosis of the sphincter of Oddi with cholangitis The ætiology of this condition is not completely understood, dilators may or may not be responsible (Cattell and Colcock 1953, Brush et al 1955, Cattell et al 1957) The terminal intraduodenal portion of the common bileduct is very delicate, and tearing of the mucosa seems very likely to lead to fibrosis

Pancreatitis —This is not uncommon in association with gallbladder disease (Weir and Snell 1935, Love 1952, Walters 1956, Cattell et al. 1957) In our experience, the condition, if found at cholecystectomy, tends to settle down subsequently, but in case 3, at re-exploration ten days after the primary operation, an inflammatory mass was found to involve the head of the pancreas Exploration of the distal end of the common bileduct at the first operation may have resulted in localised pancreatitis from incidental trauma

Recurrent stone —At a secondary operation, seven years after cholecystectomy, stones were found in the common duct in case 4 Since the symptoms dated from a cholecystectomy (for acute cholecystitis) when the common bileduct was not explored, the stones were probably missed at the primary operation Case 13 almost certainly has a stone in the duct, and awaits operation

Conditions caused by operation —Adhesions arose in cases 5 and 7

Results Related to Reasons for Cholecystectomy

There was complete relief of symptoms in 102 (76%) of 134 patients who underwent cholecystectomy having presented with severe pain (table III) Only 2 now have significant symptoms due to biliary-tract lesions

36 patients had jaundice before operation, 30 (83%) of these are now totally symptom-free and only 2 have residual biliary symptoms of any consequence

We had intended to study patients with " biliary dyskinesia ", but we have been unable to find one We conclude that this condition does not arise where cholecystectomy is done for such reasons as in this series

No normal gallbladders were removed, but in 27 gallbladders (containing stones) the walls looked normal at operation (table III) 7 patients (26%) in this group had significant post-cholecystectomy symptoms—a rather higher incidence than in the whole series (14%) The symptoms were not due to disease in the biliary tract, except possibly in 1 case, but, since 1 in 4 in this group have had a poor result from cholecystectomy, it seems that, if a normal-looking gallbladder with stones is found at laparotomy, other lesions (which may be the cause of symptoms) should be sought

Intravenous Cholangiography

This was done in 13 of the 20 patients with significant symptoms The common bileduct was not displayed in 2 cases, in the remaining 11, no cystic-duct stumps were seen

The ducts were moderately distended (15 mm and 17 mm) only in cases 7 and 13 Dilatation of the common bileduct in man has not been found after cholecystectomy by us or other workers lately (Sandweiss and Fulton 1955, Hardie and Israelski 1956, Shehadi 1957)

Summary and Conclusions

The reasons for cholecystectomy have been examined in 141 patients, whose postoperative progress has been studied for one to seven years

No gallbladder was removed unless it contained stones or was obviously diseased

121 (86%) of the 141 patients were symptom-free after operation

Significant symptoms were found in 20 patients (14%), but, in all except 2, the causes were extrabiliary In 2 others, symptoms may have been caused by operation Symptoms due to biliary-tract lesions in 4 more patients had been cured before follow-up

No evidence was found of " biliary dyskinesia "

The use of the term " post-cholecystectomy syndrome " does not seem justified

We thank Prof C F W Illingworth for his interest and for facilities to make this study

EFFECT OF CORTISONE ON DEVELOPMENT OF DIABETIC ACIDOSIS

N Kalant *
M D Toronto

From the McGill University Clinic of the Royal Victoria Hospital, Montreal

Because of the hyperglycæmic effect of adrenal steroids, there has been much interest in the role of the adrenal cortex in the development of diabetic keto-acidosis It has been suggested on the basis of animal experiment that activation of the adrenal cortex may be a consequence of insulin deprivation (McArthur et al 1954b) and in turn hasten the development of diabetic acidosis (McArthur et al 1954a) In man, on the other hand, it is clear that excess 17-OH steroids may induce (Conn et al 1948, Sprague et al 1949, Bookman et al 1953) or aggravate (Perera et al 1949) a diabetic state, and may be associated with insulin resistance (Sprague et al 1949), but rarely lead to keto-acidosis (Conn and Fajans 1956) Because of these apparent discrepancies between human and animal studies the present work was undertaken to study specifically the effects of excess cortical steroids on the development of acidosis in diabetic patients

Methods

8 patients, of ages ranging from 8 years to 65, were studied in hospital In 7 the diabetes was reasonably well controlled by diet and insulin, but in 1 (case 8) it was of the " brittle " type

---

* Medical Research Fellow, National Research Council, Canada Present address Jewish General Hospital, Montreal

The patients fasted for thirty-nine hours (from supper of day 0 to 10 A M on day 2) during which time water was allowed ad libitum, but no insulin was administered Blood samples were taken at 9 A M and 9 P.M on day 1, and at 9 A M on day 2, and analysed for sugar, total ketones, CO_2-combining power, and, in case 8, esterified fatty acids In 5 patients an intravenous glucose-insulin tolerance test was done at the end of the period of fasting All the urine excreted during day 1 was collected and analysed for sugar, total nitrogen, creatinine, sodium, and potassium After an interval of three to seven days, during which the diet and insulin dosage were the same as those previously established, the experiment was repeated as before except that cortisone acetate was given by mouth in a dose of 50 mg every four hours beginning at 8 A M on day 1, and ending at 8 A M on day 2 (total 350 mg), the last dose thus being administered an hour before the glucose-insulin test

Ketones (β-hydroxybutrate, acetoacetate, and acetone) were measured by the method of Lester and Greenberg (1948), blood-sugar by that of Folin (1929), CO_2-combining power by that of Van Slyke and Cullen (1917), urine nitrogen by a semi-microkjeldahl procedure, sodium and potassium by flame photometry, chlorides by the method of Wilson and Ball (1928), creatinine by the method of Peters (1942), and serum-esterified-fatty-acids by the method of Bauer and Hirsch (1949) Intravenous glucose-insulin tolerance tests were performed by *giving an intravenous injection of 10 g* of glucose with crystalline insulin 8 units over a period of two minutes, blood was then obtained at twenty, forty, and sixty minutes after the injection The slope of the line relating the logarithm of the blood-sugar content to time was taken as an index of the response to insulin

Results

Cortisone caused an elevation in blood-sugar in all but 2 patients (cases 6 and 8) (figs 1 and 2) It had no consistent effect on ketonæmia or CO_2-combining power and did not alter the serum-fatty-acid content in the 1 patient in which this was measured (case 8) The effect on insulin responsiveness was variable (fig 3), it was diminished in 3 out of 5 patients

In accordance with many previous observations, cortisone resulted in variable increases in urinary excretion of nitrogen and potassium Glucose excretion was significant in only 2 patients during the control day of fasting, and cortisone produced a striking increase in both

Discussion

The development of diabetic acidosis is associated with increased urinary excretion of corticoids (McArthur et al 1950, Stowers 1951) Though some of this increase may be a renal phenomenon, related to the diuresis usual

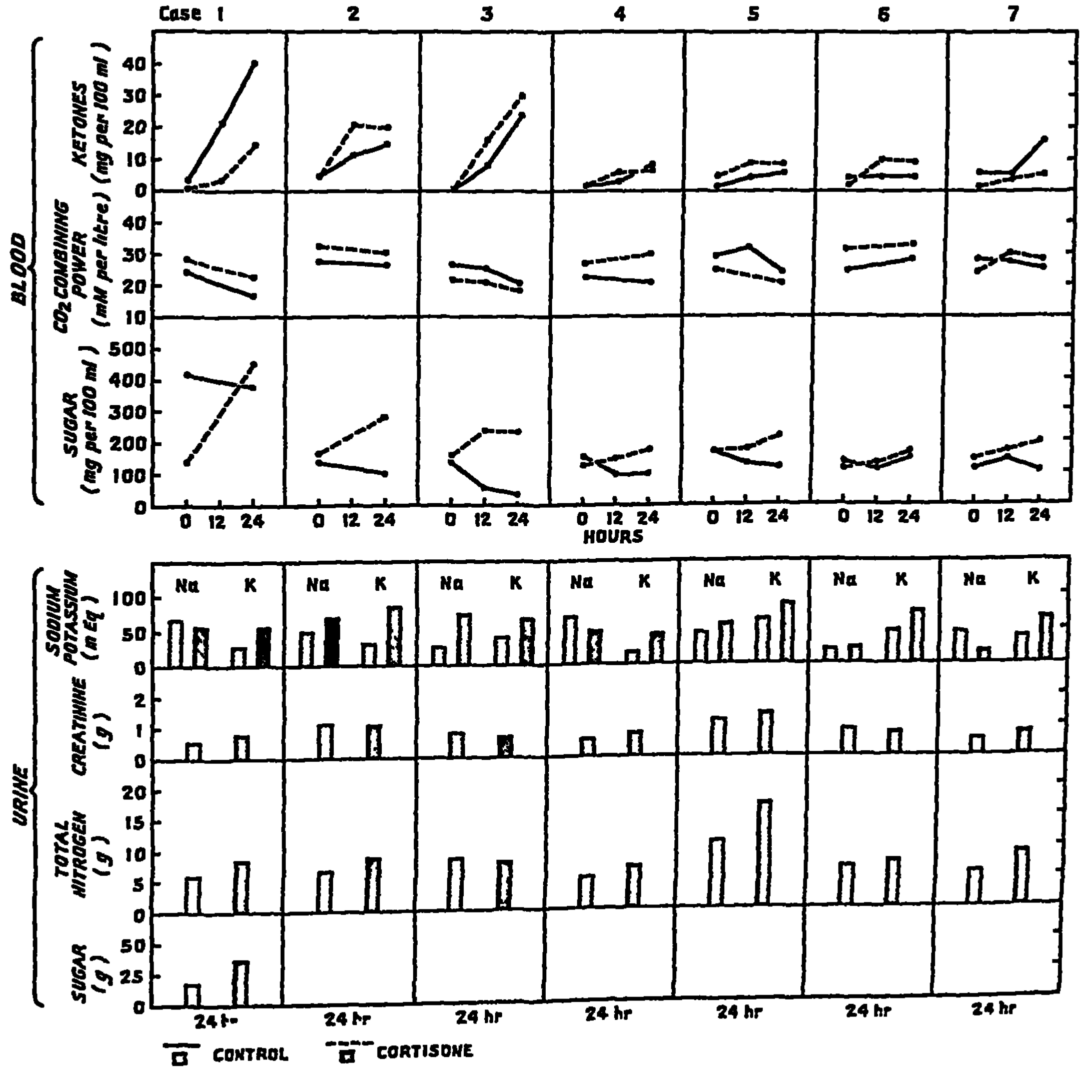

Fig 1—Metabolic effects of cortisone during fasting in 7 diabetic patients deprived of insulin Cortisone was given orally in a dose of 50 mg every 4 hours, beginning at 0, to a total dose of 350 mg

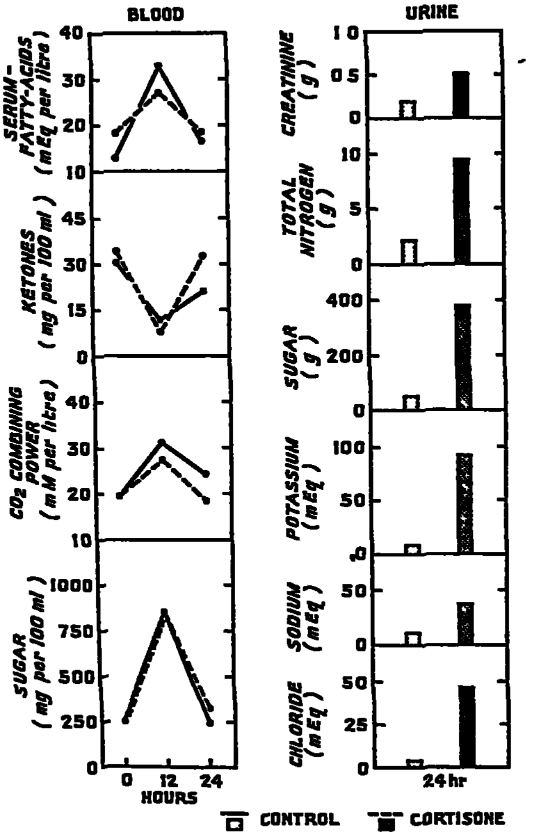

Fig 2—Metabolic effects of cortisone during fasting in a "brittle" diabetic patient (case 8) deprived of insulin. Cortisone administered as in fig 1

in the early stages of diabetic acidosis (Kalant 1955), the finding of elevated plasma-levels of free and conjugated 17-hydroxysteroids (Klein et al 1955, Wallach et al 1957) suggests that it is at least partly due to increased adrenal activity Subsequent work showed that in diabetic dogs stimulation of the adrenal cortex increased the severity of the tissue katabolism caused by withdrawal of insulin, and led to the conclusion that adrenal hyperactivity may hasten the development of diabetic acidosis (McArthur et al 1954a) Thus it was suggested that insulin lack was a "stress" which activated the adrenal, and the adrenal in turn aggravated the metabolic effects of the insulin deficiency

The present observations agree essentially with those obtained in dogs (McArthur et al 1954a) and show simply that the well-known effects of cortisone on tissue katabolism, electrolyte excretion, and insulin responsiveness are seen during development of acidosis as under normal circumstances Neither here in man, nor in the earlier work with dogs, was an increase in adrenal steroids shown to hasten the onset of ketonæmia or of acidosis (as manifested by a decrease in CO_2-combining power)

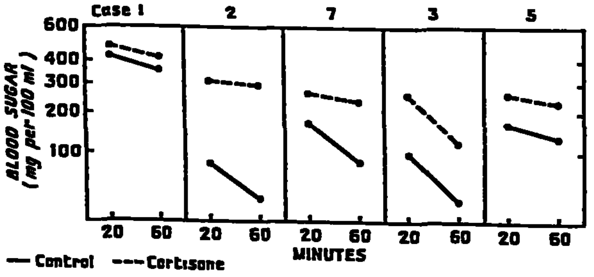

Fig 3—Effect of cortisone on insulin sensitivity in fasted diabetic patients. The slope of the line relating blood-sugar to time was determined after intravenous injection of glucose (10 g) and insulin (8 units), the greater the slope, the greater the insulin effect.

The lack of effect on acid-base balance may be due not only to the suppression of ketonæmia (Kinsell et al 1951), which is probably caused by increased peripheral utilisation of ketones (Kalant, unpublished), but also to the fact that the electrolyte disturbances usually produced by excess adrenal steroids result in alkalosis

A longer experimental period might have shown that, by causing hyperglycæmia and an increase in glycosuria, cortisone would hasten the depletion of body carbohydrate stores and so indirectly speed the development of ketonæmia. But even in case 8, where cortisone caused a very large excretion of glucose, there was no indication of more rapid production of acidosis

These observations suggest that adrenal cortical hormones should not be regarded simply as insulin antagonists, but rather that their overall effect in diabetes is a balance between anti-insulin action (increasing glycæmia and perhaps decreasing insulin responsiveness) and antiketonæmic, anti-acidotic action

Summary

Cortisone was administered to 8 diabetic patients during a twenty-four-hour period of insulin and food withdrawal, to determine its effect on the development of ketoacidosis

The steroid produced increased glycæmia, insulin resistance, and tissue katabolism, but did not increase ketonæmia or decrease the carbon-dioxide combining power

It is concluded that cortical steroids do not contribute significantly to the development of diabetic ketoacidosis

I am indebted to Dr F McCall and Dr E Harpur for permission to study patients in the wards of the Montreal Children's Hospital

CHROMATIN-POSITIVE KLINEFELTER'S SYNDROME (PRIMARY MICRORCHIDISM) IN A MENTAL-DEFICIENCY HOSPITAL

M A Ferguson-Smith
M B Glasg

SENIOR HOUSE-OFFICER IN PATHOLOGY, DEPARTMENT OF PATHOLOGY, THE UNIVERSITY, AND WESTERN INFIRMARY, GLASGOW

Low intelligence was found in some patients with Klinefelter's syndrome studied at a male-infertility clinic at this hospital (Ferguson-Smith et al 1957), the origin of these cases naturally excluded major mental defect A review of the published reports at this stage revealed several cases of oligophrenia associated with the syndrome, one of the original patients of Klinefelter et al (1942) was feebleminded and another unintelligent Pasqualini et al (1957) found 11 feebleminded among their 31 patients with Klinefelter's syndrome

In none of the previously published cases does the nuclear sex seem to have been investigated At the infertility clinic only patients with female nuclear sex showed significantly subnormal intelligence This suggested that a more severe degree of mental deficiency might exist in other cases Such patients would tend not to marry, far less to attend an infertility clinic, some might even require institutional care Accordingly, 325 mentally defective males at Lennox Castle Hospital were tested by the oral-mucosal smear technique of nuclear sexing (Moore and Barr 1955) I report here the results of this survey, including more detailed investigations of 4 patients found to have female nuclear sex The youth of 2 of these patients made it possible to draw further conclusions about the nature of the syndrome

TABLE I—NUCLEAR SEX AND GRADE OF MENTAL DEFECT IN 325 MALE MENTALLY DEFECTIVE PATIENTS

Group and grade of mental defect	Nuclear sex: Chromatin-positive (female)	Nuclear sex: Chromatin-negative (male)	No of patients
Partially selected sample			
Feebleminded	1	6	42
Imbecile	0	35	
Idiot	0	0	
Unselected sample			
Feebleminded	2	125	283
Imbecile	0	118	
Idiot	1	37	
Total	4	321	325

Methods and Materials

The initial group of patients was collected for me by one of the medical staff from among the ambulant patients, it was partially selected because he intentionally included an excess of patients thought to present clinical hypogonadism (table I) The discovery of female nuclear sex in case 4 (table II) prompted the study of further cases, taken from each of the main grades of mental defect but otherwise unselected This larger sample included 65 low-grade defective children from a branch hospital and 62 high-grade educable defective children, in the additional hope of discovering prepubertal cases of Klinefelter's syndrome The remainder consisted of the whole population of several male adult wards at Lennox Castle

An oral smear was obtained from each patient, and the degree of mental defect was recorded, no other investigation or examination was made except in the 4 cases with female nuclear sex, and in these only after this diagnosis had been confirmed Results of certain of these investigations are shown in table II No attempt was made to discover chromatin-negative cases of Klinefelter's syndrome (with male nuclear sex)

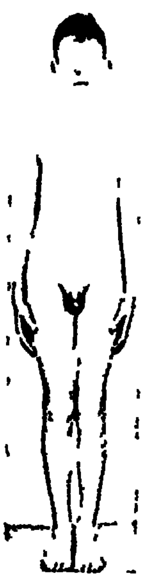

Fig. 1—Case 1, aged 14

Clinical Findings

Case 1 —A boy aged 14 (fig 1) was admitted in July, 1957, as a feebleminded person beyond parental control, with a mental age of 9½ years He is of average height and weight for his age but has particularly small testes and no development of secondary sex characteristics There is no gynæcomastia

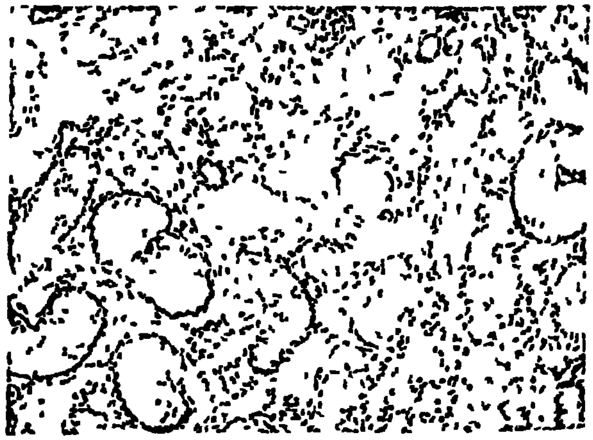

Fig 2—Case 1 testicular biopsy specimen showing numerous small completely hyalinised ghost tubules, scanty Leydig cells; occasional immature tubules lined by undifferentiated Sertoli cells; and complete absence of germ cells (Masson × 80)

Histology —Right testicular biopsy showed numerous small immature seminiferous tubules lined solely by undifferentiated

* Assessed by the Stanford Binet test † Low level of development prohibited more detailed assessment.

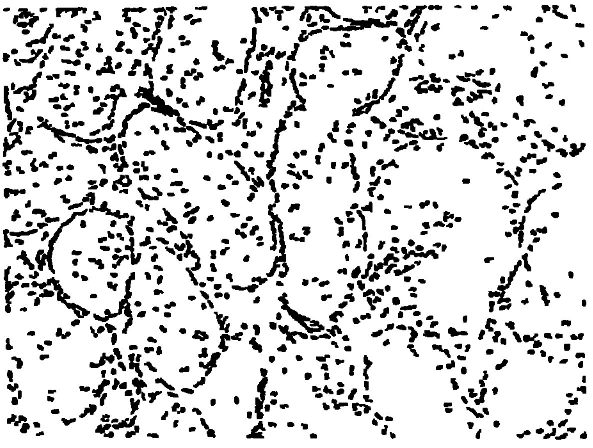

Fig 3—Case 2 testicular biopsy specimen showing immature tubules without germ cells (left) and several tubules showing scanty spermatogenesis (right), Leydig cells slightly increased and no hyalinisation of tubules. (Haematoxylin and eosin × 80)

Sertoli cells There were occasional small completely hyalinised "ghost" tubules, and Leydig cells could just be recognised In one tubule several spermatogonia and a few primary spermatocytes were seen Left testicular biopsy (fig 2) showed that a third of the tubules were small "ghost" tubules, Leydig cells were more obvious but not present in excess Sections stained by Weigert's elastic method showed a normal proportion of elastic fibres around the Sertoli-cell-lined tubules but a complete absence of elastic tissue in or around the small "ghost" tubules

Case 2—A boy, aged 14½, who was admitted at the age of 6 years, is an idiot, has frequent epileptic seizures, and is doubly incontinent His secondary sex characteristics are moderately well developed; his external genitalia are adolescent, and pubic and axillary hair are present. His testes are small There is no gynæcomastia

Histology—The histological appearances of testicular biopsy material (fig 3) were remarkable, most of the seminiferous tubules had no germ cells and were lined by Sertoli cells only No "ghost" tubules were found, and there was no evidence of any hyalinisation of the tubules A considerable proportion of the tubules (at least 20% of those in the right testis) showed active but scanty spermatogenesis to the spermatid level The number of Leydig cells was slightly increased

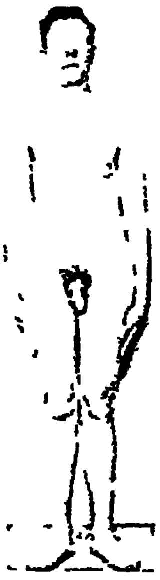

Fig 4—Case 3, aged 28

Case 3—A man aged 28 (fig 4) had been excluded from the ordinary school at the age of 11 years and had attended special schools, but his conduct was most unsatisfactory, and he was admitted to Lennox Castle as a feeble-minded person in need of institutional care He presented the typical features of Klinefelter's syndrome, with moderate bilateral gynæcomastia and small testes His prostate was impalpable

Histology—Testicular biopsy showed Sertoli-lined tubules among large aggregates of abnormal Leydig cells, most of the tubules were small "ghost" tubules identical in size and appearance with those seen in case 1 Scanty spermatogenesis, with maturation to spermatocytes only, was seen in two tubules A section stained for elastic tissue (fig 5) showed normal amounts around the Sertoli-lined tubules but none around the "ghost" tubules

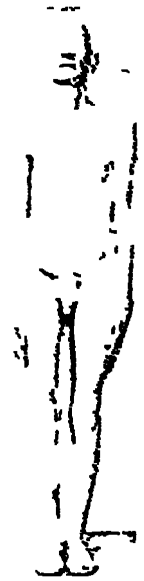

Fig 6—Case 4, aged 52.

Case 4—A man aged 52 (fig 6) had been involved in numerous homosexual incidents before admission to the Hospital at the age of 19 During the past twelve months he has complained of early fatigue and is losing weight His skin is smooth and soft, and there is general lack of body, facial, and axillary hair, definite slight bilateral hyperplasia of breast tissue is present, the testes are soft and small, and the prostate is impalpable The patient looks at least twenty years older than his actual age

Histology—Bilateral testicular biopsy showed an almost complete absence of recognisable testicular tissue Biopsy of his left testis showed only the hyalinised "ghosts" of tubules in an amorphous connective-tissue stroma, there were no Leydig cells Biopsy of his right testis showed a similar condition with the addition of a single small well-vascularised island of abnormal Leydig cells constituting the only sign of activity Weigert's elastic stain revealed two types of "ghost" tubules (1) most of them were small "ghost" tubules without elastic tissue, identical with those observed in cases 1 and 3, and (2) very much larger "ghost" tubules (fig 7) containing a considerable quantity of elastic tissue, and of about the same size as the Sertoli-cell-lined tubules in case 3 (fig 5), resembling the completely atrophic tubules commonly found at necropsy in the testes of elderly men In this case the diagnosis of nuclear sex from the blood-cells would have been misleading (table II)

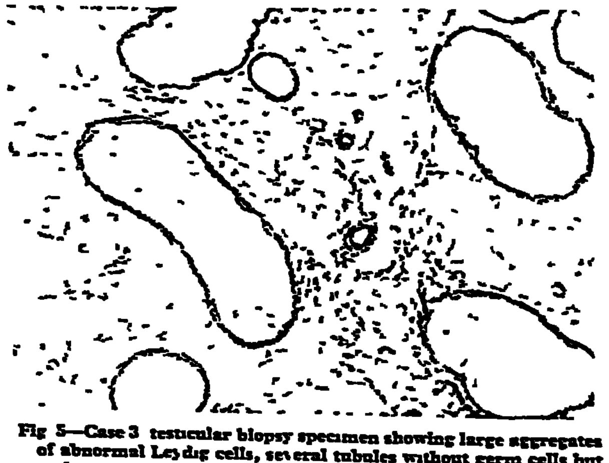

Fig 5—Case 3 testicular biopsy specimen showing large aggregates of abnormal Leydig cells, several tubules without germ cells but with normal amounts of elastic tissue and small ghost tubules with no elastic tissue (centre). (Weigert's elastica. × 80)

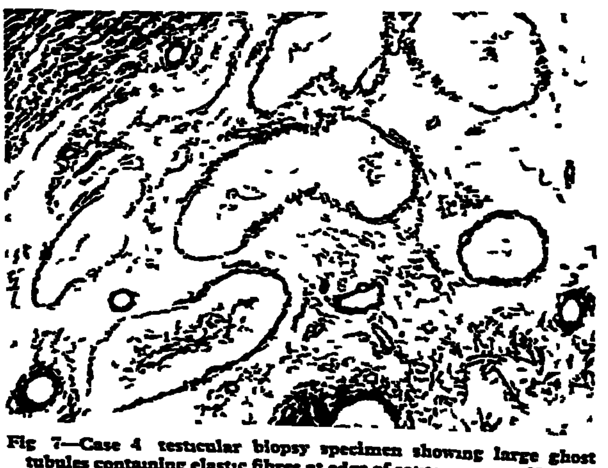

Fig 7—Case 4 testicular biopsy specimen showing large ghost tubules containing elastic fibres at edge of solitary mass of Leydig cells (lower right) Compare with fig 5 (Weigert's elastica. × 80)

Family Studies

The families of these 4 patients were investigated with particular reference to hereditary factors and to ætiological factors operating either during pregnancy or in early childhood No evidence of inheritance of Klinefelter's syndrome was found As is usual in such cases, an explanation of the disability was offered in each case

The mother of case 1 had active pulmonary tuberculosis during her pregnancy

The mother of case 2 conceived at the age of 43 and was treated during the first five months of her pregnancy with stilbœstrol and barbiturates in the mistaken belief that her symptoms were due to the menopause

It was claimed that case 3 was well until involved in a serious street accident at the age of 9 years

The mother of case 4 was aged 46 when she gave birth to the child prematurely after antepartum hæmorrhage

A family history of mental defect was found in case 1 only, the mother having two feebleminded stepbrothers There is a history of twins in the families of cases 2, 3, and 4 but none of the propositi is a twin, and at present there is no evidence to regard this as more than an incidental finding The relatively advanced maternal age at the time of conception in 2 cases, and the chronic illness during pregnancy in 1 other, are noteworthy in view of the hypothesis of Witschi et al (1951), who suggest that " blastophthoria " may be the primary cause of chromatin-positive Klinefelter's syndrome

Discussion

Incidence

It has previously been shown that patients with chromatin-positive Klinefelter's syndrome form 3% of all subfertile patients attending a male-infertility clinic (Ferguson-Smith et al 1957), and further calculations based on this material suggest that the incidence of these patients among the general population is at least 1 in 10,000 The present survey seems to indicate that the incidence is higher among mentally defective persons than in the general population Although the present series is too small to form the basis for a precise figure, it is not unreasonable to suppose that about 1% of male mentally defective persons requiring institutional care have female nuclear sex In fact, chromatin-positive Klinefelter's syndrome appears to be one of the commonest conditions associated with primary amentia yet described in males

Pathogenesis

In spite of its small size this series is important in relation not only to mental defect but also to the histogenesis of Klinefelter's syndrome

The great majority of previously published cases have been in young adults because, under normal conditions, it is only young adults who present themselves for investigation with this disorder (Nelson 1956) In the present series the oral-mucosal-smear technique of nuclear sexing as a screening test has led to the discovery of 2 younger patients and 1 older patient, and the testicular histology in these patients is especially interesting (But for this survey case 1 would have been considered to be an example of delayed puberty, and case 2 would have been entirely missed)

Certain conclusions may be drawn from examination of the testicular biopsies in these cases

(1) *The condition begins before puberty* —The hypothesis that a disturbance of Leydig cells at puberty causes hyalinisation of the seminiferous tubules and progressive atrophy of the germinal epithelium (De la Balze et al 1952) can no longer be held Although case 2 is postpubertal, no hyalinisation of tubules was found, and there was a complete absence of germ cells in most of the tubules In case 1, despite the prepubertal findings, completely hyalinised " ghost " tubules and a scarcity of Leydig cells were very striking features on left testicular biopsy The absence of elastic tissue in these " ghost " tubules may be taken as evidence that where the tubules degenerate they do so long before puberty The results of work in progress, extending the studies of De la Balze et al (1954), indicate that these elastic fibres normally appear in the tunica propria at about the age of 10 years Degeneration after this age, as in some of the tubules in case 4, produces larger " ghost " tubules with persistent elastic tissue (fig 7) Therefore treatment at puberty can no longer be expected to prevent sterility in adult life, because the germ cells are absent far earlier

(2) *Hyalinisation of the seminiferous tubules is not invariable in Klinefelter's syndrome* —Hyalinisation of the seminiferous tubules has long been considered to be characteristic, if not pathognomonic, of testicular biopsies in Klinefelter's syndrome Its absence in case 2 indicates that this is not an essential criterion and explains the relatively larger size of the testes in this patient

(3) *A considerable reduction in the number of germ cells appears to be the most significant defect* —Normally it is possible to identify spermatogonia in the supporting epithelium of the seminiferous tubules from a very early stage of embryogenesis, through infancy and childhood, up to the age of onset of spermatogenesis The scarcity of germ cells in these 2 younger patients suggests that there was either an initial failure of germ cells to reach the developing gonad during gonadogenesis or a selective destruction of germ cells at a later stage (but before puberty) The variable degree of damage to the tubules possibly supports the latter hypothesis Spermatogenesis is considered to be rare in Klinefelter's syndrome, therefore it is remarkable that it was found in 3 of the 4 present cases Maturation of germ cells was incomplete in each case, but mature spermatozoa have previously been reported in association with female nuclear sex in 3 cases (Bunge and Bradbury 1956, Nelson 1956, Ferguson-Smith and Munro 1958) The proportion of tubules showing spermatogenesis in case 2 (fig 3) is striking, and the theoretical possibility of fertility in such a person is not so remote as might previously have been imagined

(4) *Severe secondary testicular atrophy with premature senility may be superimposed* —Case 3 presents a hitherto undescribed appearance of one of the later stages of the natural history of Klinefelter's syndrome At a comparatively early age there was a complete failure of the gonads, with atrophy of the remaining tubules, which became large " ghost " tubules, and disappearance of Leydig cells, associated with symptoms of androgen deficiency

Although more cases must be studied before more definite conclusions can be drawn, it appears that the most significant change at puberty is hyperplasia of the Leydig cells Further surveys of the type described here will almost certainly reveal earlier stages of Klinefelter's syndrome and improve our knowledge of its pathogenesis

Nomenclature

Since the discovery that only some of the patients with Klinefelter's syndrome have female nuclear sex it is clear that the syndrome can no longer be considered to be a single entity and must be critically reassessed (Nelson 1957) Alternative names, such as " seminiferous tubule dysgenesis " (Grumbach et al 1957), " female pseudohermaphrodites with gonadal dysgenesis ", and " pseudomales " (Witschi et al 1957), are either insufficiently descriptive or may be misleading, none has any particular clinical significance

It has been found of practical value in this area (where 36 chromatin-positive cases have been discovered in the past eighteen months) to consider the classification from the clinical viewpoint The problem that presents is essentially the differential diagnosis of a patient with small testes—the one invariable finding in Klinefelter's syndrome Thus, all cases recognised in this way and showing no evidence of secondary testicular atrophy or of pituitary disease are classed as primary microrchidism and, on the basis of nuclear sexing, subdivided into chromatin-negative and chromatin-positive microrchidism

Sterility and microrchidism are constant features of the syndrome, variable findings include gynæcomastia, azoospermia, eunuchoidism, increased urinary excretion of gonadotrophins, and decreased excretion of 17-ketosteroids In view of the findings described here, mental defect and hyalinisation of the seminiferous tubules must now be added to the list of variable features, at least in chromatin-positive microrchidism

Summary

By the oral-mucosal-smear technique of nuclear sexing of 325 male patients at a mental-deficiency hospital were found to have female nuclear sex 3 were feeble-minded, and 1 was an idiot

Findings in 2 patients aged 14 are of especial interest as regards the pathogenesis of Klinefelter's syndrome

Primary microrchidism is suggested as a name for the condition

I am grateful to Dr Ronald C MacGillvray, physician-superintendent, Lennox Castle Hospital, for permission to publish and for guidance throughout the investigation, and to members of his medical and nursing staff, especially Dr J Campbell and Dr G L Ligertwood I am also indebted to Mr W S Mack for admitting the patients under his care and for the testicular biopsies, to Dr A B Telford Govan for the hormone assays, to Mr Andrew McGhie for intelligence testing, to Mr Norman L Russell for technical assistance, and to Mr G Kerr for the photomicrographs Cases 3 and 4 were reported at the Symposium on Nuclear Sex in September, 1957

GASTRIC CANCER AND ATHEROSCLEROSIS

N Dungal
M D
PROFESSOR OF PATHOLOGY
Thorgils Benediktsson
M D
ASSISTANT IN MORBID ANATOMY
UNIVERSITY OF ICELAND, REYKJAVIK

In a series of papers Elkeles (1949, 1950, 1953, 1956) has pointed out that between gastric carcinoma and aortic calcification a certain relationship exists which may be of diagnostic importance According to his investigations peptic ulcer of the stomach is in a high percentage of cases accompanied by calcification of the aorta in elderly people, 64% of people aged more than 50 showing roentgenological signs of calcification, whereas patients of the same age-group with gastric cancer show much less or no calcification

Busch (1924) had already concluded that aortic sclerosis was less pronounced in cancer patients than in other people of the same age-group, and Casper (1932) corroborated this finding

Since gastric carcinoma is common in Iceland but arteriosclerosis is much less common there than in many other countries (Dungal 1936, 1953, 1955) we examined our necropsy material with a view to studying the relationship between gastric cancer and aortic sclerosis

Material

Since aortic sclerosis is only exceptionally seen in persons aged less than 50 in Iceland, and since other workers have mainly limited their statistics to persons aged more than 50, we decided to limit our quest also to those aged 50 or more In this age-group there were 1430 necropsies in 1934–56, including 149 cases of gastric carcinoma Since, however, the descriptions of the aorta were insufficient for our purpose in 320 cases, among which were 45 of stomach cancer, and 77 cases in which the description of the stomach and/or duodenum was insufficient, there remained 1033 cases containing satisfactory descriptions of stomach, duodenum, and aorta Of these 480 were in females and 553 in males

Classification

The condition of the aorta was classified into four stages 0, smooth, without intimal changes, +, atheromatous patches without noticeable calcification, ++, atheromatosis and calcified plaques, and +++, much calcification The results are shown in table I

TABLE I—GASTRIC CANCER AND AORTIC SCLEROSIS

Age (yr)	Sex	No of cases	Atheromatosis and calcification of aorta				Percent calcification (++ and +++)
			0	+	++	+++	
50–60	F M	11 20 } 31	7 14 } 21	4 6 } 10			
61–70	F M	18 29 } 47	4 14 } 18	7 9 } 16	6 6 } 12	1	38 9 20 7 } 27 7
71–80	F M	6 10 } 16	1 2 } 3	5	4	1 3 } 4	83 3 30·0 } 50 0
81–100	F M	4 6 } 10	1 2 } 3	1	1 2 } 3	2 1 } 3	75 0 50 0 } 60 0
Total	F M	39 65 } 104	13 32 } 45	11 21 } 32	11 8 } 19	4 4 } 8	38 5 18 5 } 26 0

Atheromatosis 32 3% Calcification 26%

In this table there are relatively many smooth aortas, not only in people age 50–60, where all are either smooth or showing slight atheromatous changes, but also in the older age-groups Even in the oldest age-groups (70 or more) there are people with relatively smooth aortas

Another striking thing in this table is the higher rate of calcification in women than in men Although the numbers are small, the lower rate of calcification at all ages in men and the total of 38% calcification in women against 18 5% in men indicate a definitely greater tendency towards calcification in women Compared with the fact that the incidence of gastric cancer in men is about double that in women, this may have some significance

Gastric Ulcer and Aortic Sclerosis

For comparison we listed all cases of gastric ulcer found in the same material and the condition of the aorta in these cases (table II) Gastric ulcers are rather infrequent in Iceland, in 3285 necropsies of patients of each sex we found only 94 (2 87 %)

Although the numbers are not large, they indicate that the incidence of atheromatosis is about the same as

TABLE II—GASTRIC ULCER (INCLUDING SCARS) AND CONDITION OF AORTA

Age (yr)	Sex	No of cases	Atheromatosis and calcification of aorta				Percent calcification (++ and +++)
			0	+	++	+++	
50–60	F	7 } 11	4 } 5	2 } 4		1	14 3 } 18 2
	M	4	1	2	1		25·0
61–70	F	4 } 12		2 } 5	2 } 4		50·0 } 41 7
	M	8	2	3	2	1	37 5
71–80	F	4 } 10		1	2 } 5	1 } 3	75 0 } 80 0
	M	6	1		3	2	83 3
81–100	F	4			1	3	100 0
50–100	F	19 } 37	4 } 8	5 } 10	5 } 11	5 } 8	52 6 } 51 4
	M	18	4	5	6	3	50 0

Atheromatosis 27 0% Calcification 51 4%

in cancer, but that calcification of the aorta is much more common (almost 100%) than in gastric cancer

Duodenal Ulcer and Aortic Sclerosis

Of duodenal ulcers we found only 17 cases, which showed the same aortic conditions as the stomach ulcers (table III)

Discussion

Our necropsy records are in agreement with those of Casper (1932), Elkeles (1949, 1953, 1956), and others, who found a considerably lower rate of aortic calcification in cancer cases

Elkeles (1956) found this not valid for lung cancer, although very pronounced for stomach cancer Neuburger (1930) found that carcinoma was but rarely associated with arteriosclerosis of the brain Wanscher et al (1951) also found considerably less arteriosclerosis in their necropsy material of 822 cancer cases than in 1013 control cases

Juhl (1955) investigated 12,355 necropsy records, of which 3725 were related to cancer, and found that aortic lesions were significantly less pronounced in the cancer cases than in the others, and this difference in calcification applied also to the coronary arteries Juhl suggests that cholesterol accumulates in the tumour and is consequently diverted from the arteries

TABLE III—DUODENAL ULCER AND AORTIC SCLEROSIS

Age (yr)	Sex	No of cases	Atheromatosis and calcification of aorta				Percent calcification (++ and +++)
			0	+	++	+++	
50–100	F	10	3	3	3	1	40 0
	M	7	2	1	2	2	57 1
Total		17	5	4	5	3	47 1

Atheromatosis 23 5% Calcification 47 1%

Casper (1932) also suggests *a direct causal relationship* between cholesterol metabolism and tumour growth and cites several workers, among them Borst (1924) and Jaffé and Eliassow (1927), who found that experimental tumours were easier to produce if the animals were fed cholesterin before and during the experiments

Roffo (1925) considered a disturbance of cholesterin metabolism as one of the determining causes which led to the imbalance terminating in cancer Elkeles (1956, 1957), on the other hand, interprets these facts as a diminished tendency to cancer in people with calcified aortas and thinks that cancer develops more easily in people with smooth aortas This explanation seems to be in better accordance with our findings We often find people aged 70 or more with smooth aortas, some with cancer and others without, whereas others of the same age-group have more or less severely atherosclerotic aortas, some with atheromatous ulcers It is unlikely that such changes would show retrogression due to mobilisation of cholesterol esters to a cancerous growth, and no such transfer has been reported

Our experience tends to confirm the explanation of Elkeles (1956, 1957), Busch (1924), and others that old people with smooth aortas are more likely to contract gastric cancer than are those with greater intimal changes Our knowledge of cholesterin metabolism is insufficient to offer a satisfactory explanation of this apparent causal relationship

Summary

In 1033 necropsies of people aged 50 years or more there were 104 gastric cancers A comparison was made between the condition of the aortas in these cases of gastric cancer and in controls of the same age (1) without cancer and (2) with ulcers In gastric cancer the incidence of atheromatosis was 32 3% and of calcification of the aortas 26%, against 31 3% and 47 3% in the controls and 27 0% and 51 4% in the ulcer cases

A causal relationship is assumed between cholesterin and calcium metabolism on the one hand and the development of cancer on the other

ANÆSTHESIA FOR RAMMSTEDT'S OPERATION

R A L LEATHERDALE
B M Oxon , F F A R C S
SENIOR ANÆSTHETIC REGISTRAR, UNITED OXFORD HOSPITALS

INFANTILE hypertrophic pyloric stenosis was not widely recognised until Hirschsprung reported 2 cases in 1877 Mack (1942) has described the evolution of its treatment Surgical treatment is now recognised as giving the best results, and the operation is the pyloromyotomy of Rammstedt (1912), which was based on earlier pyloroplasty procedures (Fredet and Dufour 1908, Weber 1910) This operation is one of the most successful in abdominal surgery, and in skilled hands a recovery-rate of about 99% is to be expected

Anæsthesia for Rammstedt's operation is still a matter of some controversy General anæsthesia is preferred by some (Page and Jewesbury 1937, Ladd et al 1916, Schaefer and Erbes 1918, Ladd and Gross 1950, Pasma 1954), and local analgesia by others (Levi 1911, Browne et al 1951, Black and Love 1957, Handfield Jones and Porritt 1957) The advantages and disadvantages of each method of anæsthesia are discussed by Black and Love (1957) I do not here intend to advocate one method to the exclusion of others, or to compare results obtained with different techniques, the series is obviously far too small for such a purpose Such comparisons (Cope 1918) have shown no significant difference in results attributable to the method of anæsthesia The choice of one or other method should depend more on the skill, preference, and ability of surgeon and anæsthetist than on the condition of the patient or on an arbitrary decision by either person

Material

Between January, 1949, and July, 1957, 150 patients with infantile pyloric stenosis were admitted to the United Oxford Hospitals and treated by Rammstedt's operation. 8 were operated on under general anæsthesia; in 6 of these 8 cases the anæsthetist concerned was more familiar with general anæsthesia than local analgesia for surgery of the newborn, and in 2 the diagnosis had not been established with complete certainty before operation. An uncertain diagnosis was regarded as a definite indication for general anæsthesia. 142 patients were operated on under local analgesia, and I intend to discuss the use of local analgesia for this operation and describe the technique that was followed. Local analgesia is preferred for two main reasons: (1) it causes less systemic upset, and (2) feeding is more rapidly re-established postoperatively and the risk of postoperative vomiting, due to the additional disturbance of a general anæsthetic, is eliminated.

In the 150 cases the proportion of boys to girls was 5:1; the distribution according to weight and age at the time of operation is shown in figs 1 and 2. The child aged 16 weeks was born 7 weeks prematurely. Eight surgeons performed the operations, but 90% of the patients were operated on by one of four surgeons. In every case the operation was carried out through a right upper trans-rectus incision.

Preoperative Treatment and Premedication

In the United Oxford Hospitals, all patients with infantile pyloric stenosis are admitted to the pædiatric wards, and the surgeon and anæsthetist are called into consultation by the pædiatrician at an early stage. The treatment is always surgical, and medical treatment with antispasmodic drugs is never tried.

The condition is not regarded as an acute surgical emergency, and a period of at least twelve hours for observation and assessment in the ward is allowed in even the fittest of infants who show no systemic upset. Should the child be seriously ill, with evidence of dehydration and alkalosis, this period of preoperative preparation is extended if necessary to correct the fluid and electrolyte balance. One very ill child was so deficient in chlorides on admission that he was having convulsions. These were stopped only by infusion of saline solution; attempts to control them with amylobarbitone sodium and paraldehyde had been unsuccessful.

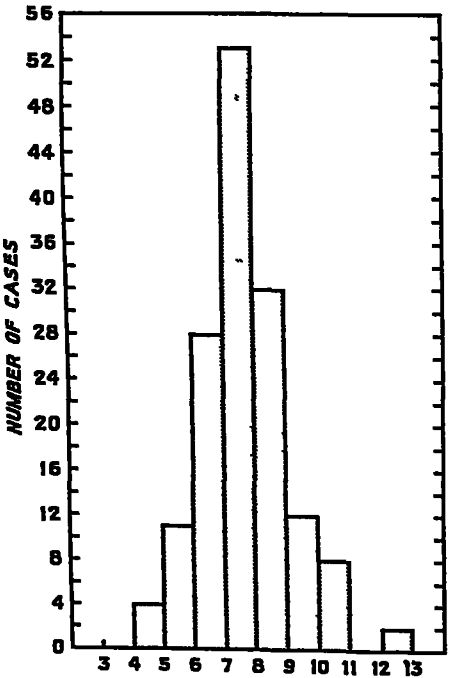

Fig 1—Weight-distribution of patients

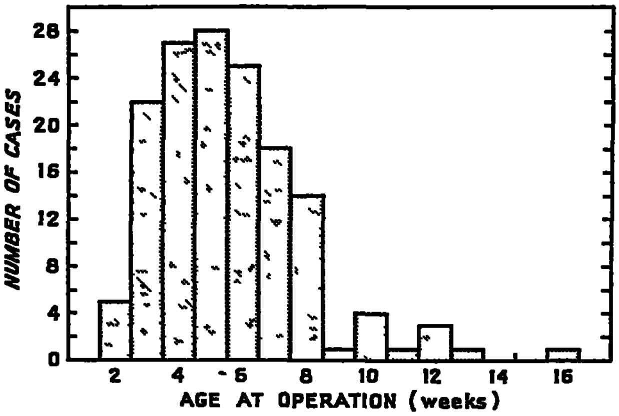

Fig 2—Age-distribution of patients

Although in this series the preoperative treatment was in the hands of the pædiatricians, this does not hold good in all hospitals. Anæsthetists are often directly concerned at an early stage with the treatment of these patients and the resuscitation of those who are gravely ill. An anæsthetist must, then, be fully conversant with all aspects of transfusion in infants. It is dangerously easy to overtransfuse a 7-lb baby.

An hour before the operation is to be performed, a rubber catheter (10 or 12 French) is passed through the nose into the stomach, which is washed out to remove any mucus or retained food. This tube should be left in position until after the operation. It prevents distension of the stomach with air—a condition that is a great hindrance to the surgeon—and is a safeguard against the regurgitation of stomach contents into the pharynx during the operation. Chloral hydrate is used for sedation and is given through the stomach-tube after the washout. It is administered as a mixture with the following formula:

Chloral hyd	gr 3
Syrup	minims 5
Aq anethi	ad 1 dram

Chloral produces its effect rapidly, since it is absorbed from the stomach, and it has a wide margin of safety. It was found advantageous to base the dosage of chloral on gr 1 per lb body-weight; such a dose quietened the child and had no dangerous depressant effects. The dose of chloral depends not only on the child's body-weight but on his fitness. In a few cases morphine gr $^1/_{80}$ (0·75 mg) was administered, but this practice was abandoned owing to the danger of respiratory depression. Atropine sulphate gr $^1/_{200}$ (0·3 mg) was given to all patients an hour before operation, except infants weighing less than 5 lb, to whom gr $^1/_{300}$ (0·2 mg) was given. No untoward reaction, attributable to the atropine, was seen in any child.

When the stomach has been washed out and the premedicant drugs given, the child is carefully bound on to a padded crucifix and left well covered in a room where the temperature is kept between 75° and 80°F until the time of operation.

Anæsthetic Technique

Since heat-loss in these patients must be kept to a minimum, the period for which the trunk is exposed for anæsthetic and surgical procedures should be as short as possible. The temperature of the anæsthetic-room and operating-theatre should be 75–80°F. Spirit should not be used to prepare the skin, and cetrimide solution

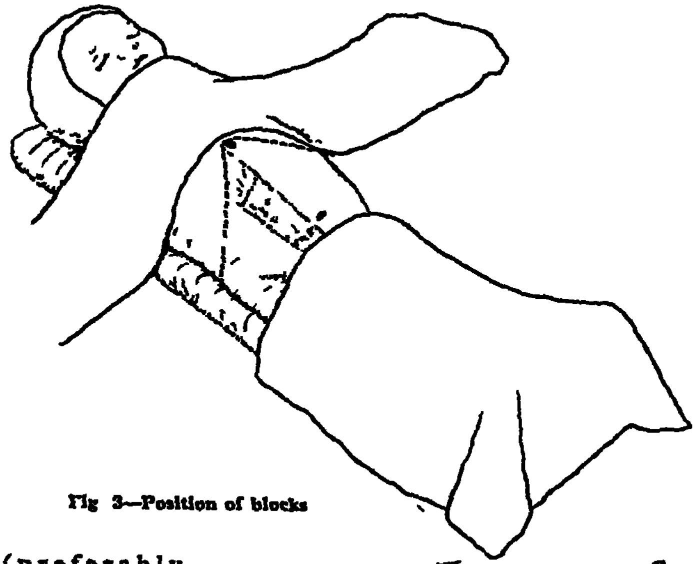

Fig 3—Position of blocks

(preferably warmed) can be advantageously used by both surgeon and anæsthetist

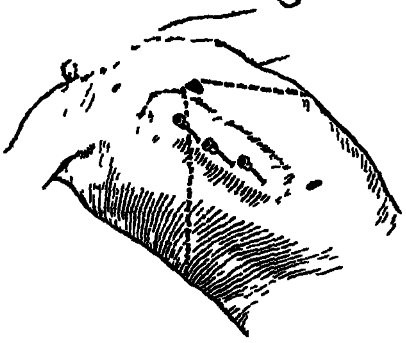

Fig 4—Area infiltrated

The area of infiltration and the blocks inserted are shown in figs 3 and 4 The subcutaneous tissues are infiltrated over the right rectus muscle from the umbilicus to a point above the coastal margin The three nerves supplying the right upper rectus muscle are blocked The tendinous intersections are intimately adherent to the anterior rectus sheath and may impede the flow of solution from one segment to the next The intersections vary slightly in position and in density of the fibrous tissue of which they are composed, and one or more may in fact be absent Since an upper right transrectus incision was used in all cases, no block of the left rectus was needed Altogether 10–12 ml of fluid is sufficient—2 ml for each block and the rest for infiltration

The drugs used were procaine, lignocaine (in nearly three-quarters of the cases), and cinchocaine (in 2 cases)

Because of possible toxic reactions to local analgesic drugs, some workers prefer general anæsthesia for Rammstedt's operation (Sington 1923, Hewer 1923), the risk of death ensuing from failure to adjust the dose of the drug to the weight of the patient was pointed out by Macintosh (1949)

The importance of using adrenaline in the solution and thus retarding absorption of the drug is often insufficiently emphasised Levi (1941) and Browne et al (1951) advocate the use of 0 5% procaine Levi, using a solution containing no adrenaline, regards 10 ml as a safe maximum volume Browne et al using a solution containing adrenaline, do not recommend the use of more than 15 ml Ward-McQuaid and Porritt (1950) use a solution containing 0 3% procaine with 1 600,000 adrenaline added, 15 ml of this solution contains 50 mg of procaine, which is a safe maximum dose for a baby of 7 lb, it is equivalent to 1 g of procaine in a 10 st adult, which is usually regarded as a safe upper limit for this drug Certainly the use of procaine in a strength of more than 0 5%, is unnecessary and dangerous

A solution of lignocaine 0 25%, containing 1/400,000 adrenaline, was used in most of the present cases and produced satisfactory anæsthesia 12 ml of this solution, containing 30 mg of the drug, is ample for a 7-lb infant, with a heavier patient the volume of solution can be increased proportionately, and with a smaller or a very sick infant the dose should be decreased

Ward-McQuaid and Porritt (1950), in their series of 100 cases, had 1 death due to procaine poisoning, 20 ml of 1% procaine without adrenaline (200 mg of procaine) was given Another patient had toxic reactions after infiltration with 25 ml of 1/1000 cinchocaine with 1/100,000 adrenaline, but this child recovered

2 babies in the present series had toxic reactions to the local analgesic drug (in each case lignocaine), in both cases the standard teaching on dosage of local analgesic drugs had not been observed, and the solutions used contained no adrenaline

An infant weighing 8 lb 11 oz, was given 12 ml of 1% lignocaine without adrenaline (120 mg of lignocaine) Convulsions and collapse followed in a few minutes and were controlled only by injecting thiopentone sodium via the jugular vein Oxygen was administered and the child recovered The operation was postponed for twenty-four hours and then successfully carried out under local analgesia using 0 25% lignocaine solution

An infant, weighing 7 lb 8 oz was given 20 ml of 0 5% lignocaine solution without adrenaline (100 mg of lignocaine) The operation was almost completed when convulsive movements of the face and limbs developed Again barbiturate was used to control the spasms and oxygen was administered The child recovered

These cases emphasise the importance of keeping the total dose of local analgesic below dangerous levels and of using a dilute solution The total weight of drug that may be safely injected depends somewhat on the strength of solution used, the more dilute the solution the slower the absorption of the drug into the blood-stream (Moore 1955) Adrenaline in the fluid still further delays the absorption, but the dose of this drug, too, must be kept as low as possible Dilutions of 1/400,000–1/600,000 are adequate, and stronger concentrations are both unnecessary and dangerous

Operation

Five to ten minutes should elapse between the final injection of local analgesic and the start of the operation, the more dilute the solution the longer it will take to exert its full effect During this period the child must be kept covered and warm If the operation is started too soon the infant can be quietened subsequently only by a general anæsthetic Before the infant is placed on the operating-table, the rubber mattress can usefully be warmed with a hot-water bottle

The use of a rubber teat containing cotton-wool soaked in a mixture of glycerin and dilute port or brandy is a time-honoured nostrum to divert the baby's attentions during the operation, but it can lead to swallowing of air if the content of the cotton-wool becomes exhausted This presents no difficulty if the stomach-tube has been left in situ, but it has been suggested that the use of a teat without a hole which has been dipped in the glycerin mixture still further lessens the tendency to aerophagy (I MacDonald personal communication) Since gastroenteritis is a serious complication of Rammstedt's operation, scrupulous attention must be paid to the cleanliness of the rubber teat and to the hands of the anæsthetist who is administering the mixture

The use of the catheter as a stomach-tube during the operation diminishes the risk of regurgitation of stomach contents into the pharynx owing to the surgeon's manipulations Regurgitated fluid can cause spasm of the larynx, particularly if the stomach still contains chloral—a substance which is very irritant to the larynx In 2 cases in this series, where the catheter was not left in the stomach, regurgitation of stomach contents produced laryngospasm that persisted alarmingly long On both occasions the operation had to be halted while the pharynx was aspirated and the child resuscitated with oxygen

Results and Discussion

There were 2 deaths in this series, both in patients who had been operated on under local analgesia

The 1st was a child, aged 8 weeks, who had been jaundiced since birth and had been admitted in the 1st week of life from a maternity hospital Pyloric stenosis developed while he was in hospital, and, although he was critically ill with steadily increasing jaundice, it was felt justified to operate on the pylorus in the hope that correction of one pathological process might improve chances of recovery from the other The operation proceeded satisfactorily, but the child died twenty-four hours afterwards At necropsy widespread necrosis of the liver was found, but the ætiology of this could not be determined This child died of liver disease and the pyloric stenosis was an incidental complication that had no real bearing on the fatal outcome

In the 2nd case, an infant aged 6 weeks, operation and the postoperative period were uneventful, and the child was discharged home on the fifth day A week after discharge an infection of the abdominal wound developed and the child was readmitted to hospital Gastroenteritis then developed and failed to respond to treatment, he died four weeks after operation This child would almost certainly have recovered if he had not been readmitted to hospital and exposed to the risk of cross-infection which caused the gastroenteritis

The mortality for this series is thus 1 3% It is, however, disturbing that failure to observe standard practice in the use of local analgesia nearly brought about 2 more deaths

Local analgesia does not provide satisfactory operating conditions in every case, in some it must be supplemented with light general anæsthesia, particularly when the abdomen is being closed Aird (1957) found general anæsthesia necessary in 1 case in 10 Of the 142 cases in this series operated on under local analgesia, 12 required general anæsthesia as a supplement Most of these 12 patients were anæsthetised by junior members of the department

Local analgesia, particularly when adrenaline is used in the solution, is regarded by some workers as inadvisable on the ground that it may impair healing of the abdominal wound and thus predispose to sepsis (Ladd and Gross 1950, Benson and Warden 1957) Of the present 142 patients operated on under local analgesia, only 3 had any sepsis and delay of healing of the wound, and in only 1 case was it necessary to resuture the abdominal incision

This series of cases follows chronologically on that published by Ward-McQuaid and Porritt (1950) They reported 11 deaths in 100 patients, and it is encouraging to note the improvement in results over recent years

Summary

Of 150 infants submitted to Rammstedt's operation 142 were operated on under local analgesia

Analgesia was induced by blocking the three nerves to the right upper rectus with, usually, 12 ml of a solution containing 0 25% lignocaine and 1/400,000 adrenaline 2 infants had convulsions when larger amounts were given

2 infants died—1 of unrelated liver necrosis and 1 of intercurrent gastroenteritis

I should like to thank Dr Victoria Smallpeice, physician in charge of the children's department, United Oxford Hospitals, for permission to quote from her records and for much advice and criticism, the surgeons, particularly Mr A Elliot-Smith and Mr A S Till, who operated on most of the cases, for their interest and assistance, Dr J V Mitchell for help in preparing this paper, and Miss Marjorie Beck for the illustrations

ST MARY'S HOSPITAL, LONDON, W 2

There are at present few means of treating Stokes-Adams attacks Only adrenergic substances and atropine are widely used, and they often have no effect on the condition or produce only temporary improvement We report here sustained improvement following the use of corticotrophin in three cases of Stokes-Adams attacks which did not respond to conventional treatment

Case-reports

Case 1 —A Civil Servant, aged 35, had experienced occasional bouts of loss of consciousness since September, 1953, in which he became pale, had twitching movements of his limbs and face, and fell to the ground He had a premonitory sensation of precordial constriction Consciousness would return after ten seconds, and this was marked by flushing of his face and sweating He had had ankylosing spondylitis since 1940 He had no history of rheumatic fever On March 29, 1954, the attacks began to occur every fifteen minutes, and next day he was admitted to the Maida Vale Hospital for Nervous Diseases, where Stokes-Adams attacks were diagnosed Ephedrine had no effect on the frequency of his seizures, but on March 31 treatment with subcutaneous 1/1000 adrenaline 0 3 ml two-hourly was begun, and he improved When intramuscular adrenaline in oil 0 5 ml six-hourly was substituted, although he remained well initially, his pulse-rate fell and became irregular, and the attacks recurred On April 2, 1954, he was again given subcutaneous 1/1000 adrenaline, and the attacks ceased He had one further attack on the morning of May 3, 1954, when he was transferred to St Mary's Hospital

On examination his blood-pressure was 100/40 mm Hg and pulse-rate 46 His heart was not enlarged The first heart sound varied in intensity Electrocardiography showed complete heart-block with right bundle-branch block

Treatment and progress—Ephedrine gr $^1/_2$ t d s was given, the dose being gradually increased to gr $^1/_2$ four-hourly by May 11 Subcutaneous 1/1000 adrenaline 0 5 ml was added when his pulse-rate fell below 50 for as long as fifteen minutes This was given three times on April 24, although he had no attacks from the time of his admission until May 12, when he lost consciousness for a few seconds only He was feeling quite well again by May 13, but on May 14 he had two typical attacks with convulsions, and complete heart-block was again present, but during the preceding six weeks serial electrocardiograms had shown partial heart-block and, on two occasions, auricular flutter

Corticotrophin therapy—Treatment with corticotrophin gel 40 units b d was now begun, and after this there was no further attack The electrocardiogram returned to normal sinus rhythm after a short period of auricular fibrillation Ephedrine was discontinued and the corticotrophin gradually reduced On July 16, 1954, the patient was discharged symptom-free and in sinus rhythm on a maintenance dose of corticotrophin 15 units b d, which was finally discontinued on April 1, 1955

Follow-up—Although he remained free from symptoms, electrocardiography on May 26, 1955, showed a lengthened P-R interval and recurrence of right bundle-branch block Treatment with cortisone 100 mg daily was therefore started, but the electrocardiogram has not changed since that date The patient has been back at work since August, 1955 Cortisone was finally discontinued on Oct 25, 1956, with no ill effect

Case 2—A plumber, aged 45, had had rheumatic fever in 1931 at the age of 20 He had his first attack of loss of consciousness in 1936 and three further attacks in June, 1954 The attacks were preceded by a warm feeling, which spread from his epigastrium over the front of his chest to his neck and head He became unconscious after a few seconds and recovered in about a minute He noticed that his heart-beat was slow and forceful after an attack, and that he had sweated profusely He was seen at a hospital, told he had epilepsy, and given diphenylhydantoin sodium and phenobarbitone He was then free from attacks until Jan 13, 1956, when they returned with increased frequency, up to forty a day, often brought on by slight exertion It was now noticed that his pulse disappeared during the attacks He was transferred to St Mary's Hospital on April 26, 1956

On examination his apex-beat was six inches from the midline in the fifth space, a systolic thrill was felt at the aortic area, and a harsh systolic murmur was maximal here but conducted to the neck and apex, a diastolic murmur was conducted from the aortic area down both sides of the sternum His blood-pressure was 140/70 mm Hg There was no evidence of heart-failure Electrocardiography showed sinus tachycardia, a P-R interval of 0 2 sec, and left axis-deviation From April 28 until May 29, 1956, the number of attacks varied from one to forty-two a day, they were typical Stokes-Adams attacks in which the pulse and heart sounds were usually absent for about 25 seconds Electrocardiography showed that, at the start of an attack, the ventricular complexes ceased abruptly without any prolongation of the P-R interval The attack ended with the establishment of idioventricular rhythm in the presence of complete heart-block, which was followed by partial heart-block and the re-establishment of sinus rhythm

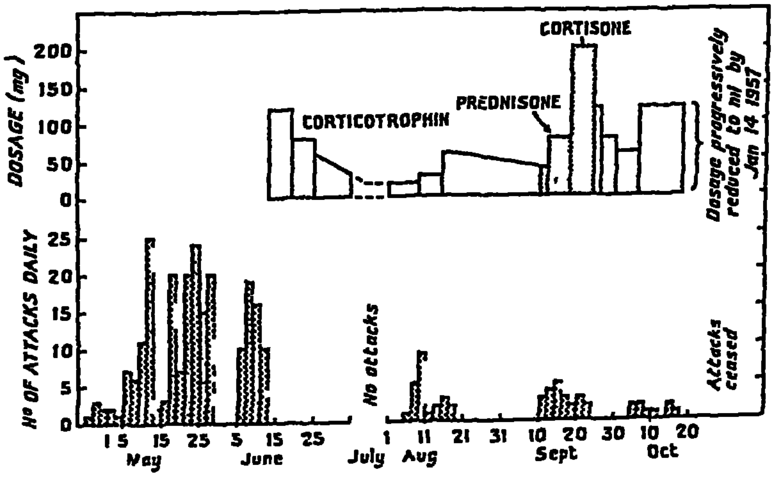
Treatment and progress—The number of attacks was apparently uninfluenced by adrenaline in oil 1 ml b d, ephedrine gr 1 q d s, methantheline 15–30 mg t d s, and atropine gr $^1/_{100}$ t d s From May 31 to June 7 there was no attack, stable complete heart-block having developed After a return to sinus rhythm on June 7 the attacks recurred and continued despite atropine gr $^1/_{60}$ t d s and digitalis folia gr $^1/_2$ t d s

Corticotrophin therapy was started on June 13, 1956, in a dosage of 30 units six-hourly, and the attacks ceased on that day The patient's response and subsequent progress are shown in the accompanying figure, which shows that the attacks recurred when attempts were made to reduce the dosage of corticotrophin, and that prednisone 60 mg daily and cortisone 200 mg daily did not control them The development of heart-failure on Oct 18, 1956, necessitated a reduction in dosage of corticotrophin until it was discontinued on Jan 11, 1957 Complete heart-block had developed on Nov 3 and continued until the patient was last seen in February No further attacks occurred until Feb 26, 1957, when he died suddenly

Necropsy findings (Prof D M Pryce)—The heart was enlarged, weighing 660 g, with healthy coronary arteries and valves except the aortic, which was narrowed and calcified and from which a calcified "buttress" extended into the ventricular muscle on the left side of the septum, near the bifurcation of the bundle of His Sections showed acute and chronic inflammation around the "buttress", which appeared to cross the bundle and its left branch The atrioventricular node was not involved

Case 3—A housewife, aged 35, was admitted to Ashford Hospital on Sept 20, 1956, complaining that in the preceding six weeks she had had at least ten attacks of faintness lasting several minutes She had noticed that lying down flat usually relieved the faintness, but on three occasions she had lost consciousness completely A week before admission sore throat with tender neck glands had developed There was a past history of growing pains and quinsies in childhood Her brother was said to have valvular disease of the heart

On examination she appeared intelligent and well but anxious Her throat was injected, and she had a subsiding herpes-simplex rash on her lips Her temperature was normal and her pulse basically regular, pulse-rate 80, but with frequent runs of irregular beats No other clinical abnormality was found Her blood-pressure during regular rhythm was 140/70 mm Hg Electrocardiography showed an auricular rate of 80 with a variable degree of auriculo-ventricular block and some dropped ventricular complexes, there was also right bundle-branch block The erythrocyte-sedimentation rate (E S R) was 17 mm in the first hour (Wintrobe), throat swabs were negative, and the antistreptolysin titre was less than 200 units per ml The level of uric acid in the blood was 3 mg per 100 ml, and blood Wassermann and Kahn reactions were negative *Cardioscopy showed nothing abnormal*



Corticotrophin therapy and progress in case 2.

Treatment and progress—During the first six days in hospital the patient had five attacks of faintness and nausea, and the irregularity of her pulse persisted On Sept 27 she had a long severe attack during which she was pale, cyanosed, and cold, sweated profusely, and had Cheyne-Stokes respiration The auricular rate was 100 a minute, and the ventricular beats were irregular at 10–18 a minute, occasionally coupled This attack did not respond to atropine, oral ephedrine, and isopropyl-noradrenaline, but after five and a half hours it was stopped by intramuscular ephedrine gr $1^{1}/_{2}$ During the next three days the patient was given oral ephedrine gr 1 and phenobarbitone gr $^{1}/_{2}$ eight-hourly and was well but for occasional palpitations and one brief syncopal attack Electrocardiography, however, confirmed the persistent presence of 2 1 heart-block, a P-R interval of 0 28 sec , and right bundle-branch block.

Corticotrophin therapy —On Oct 2, 1956, the patient had another long attack, similar to that of Sept 27 but with frequent periods of ventricular asystole accompanied by loss of consciousness and twitching On this occasion there was no response to intramuscular ephedrine She was therefore given intramuscular crystalline corticotrophin 40 units at 1 45 P M. At 6 P M her pulse-rate began to rise, the irregularities diminished, and her condition quickly improved By 8 P M 2 1 heart block was re-established, the ventricles beating regularly at 45 per minute The patient was now given corticotrophin gel 30 units twice daily, with a low-sodium diet and supplementary potassium, and from this time onwards she was symptom-free On Oct 3 the P-R interval was normal (0 2 sec) for the first time since her admission thirteen days previously By Oct. 4, 2 1 heart-block was abolished, and tracings made between Oct. 6 and Oct 12 showed the gradual elimination of right bundle-branch block. Sinus bradycardia (50 a minute) persisted until Oct. 19, seventeen days after the start of corticotrophin treatment The dose had by then been reduced to 10 units daily, and corticotrophin was finally discontinued on Oct 20 She remained well, with a normal pulse-rate, heart signs, and electrocardiogram until her discharge on Nov 3, 1956

Follow-up —She had had no recurrence of symptoms when she last visited the hospital, on July 15, 1957, though right bundle-branch block had returned for a short period and the E S R had remained raised

Discussion

Even in the untreated patient, the frequency and severity of Stokes-Adams attacks may change unpredictably, and spontaneous remissions are known to occur The success of any treatment is therefore difficult to establish Nevertheless it is unlikely that the improvement which followed corticotrophin therapy was due to chance in any of these cases

In case 1 an unstable cardiac rhythm of at least six weeks' standing was converted to a stable rhythm within six days of the first injection

In case 2 attacks which had occurred with a frequency of one to forty a day for many weeks stopped within a few hours of the first injection, and recurred twice when the dose was reduced

The attacks of syncope in case 3 were far less numerous but had been occurring for eight weeks, and electrocardiography during the last twelve days had consistently shown grossly abnormal conduction. The attacks ceased within six hours of the first injection and the electrocardiogram rapidly returned to normal

To these may be added a case published by Prinzmetal and Kennamer (1954)

Their patient, a man aged 60, had had numerous attacks of ventricular asystole for a week, following a posterior cardiac infarction Sinus rhythm was restored a few hours after a single injection of corticotrophin 40 mg , and a recurrence of heart-block a few days later was again abolished by treatment with corticotrophin After a ten-day course no further recurrence took place.

A very similar case has been reported by Phelps and Lindsay (1957), who used cortisone instead of corticotrophin

When the cause of a disorder is unknown, any discussion of the mechanism by which a method of treatment may influence that disorder must of necessity be speculative Corticotrophin was used in our three patients because it seemed possible that their heart-block was due to inflammation of the bundle of His

Case 1 had ankylosing spondylitis, a disease in which carditis is known to occur (Bernstein and Broch 1949)

In case 2 the presence of aortic stenosis of rheumatic origin suggested that the bundle might be damaged by a rheumatic lesion.

The origin of case 3's heart-block was more obscure, but her malaise, herpes simplex, and raised E S R. all pointed to infection as an underlying cause

In Prinzmetal and Kennamer's (1954) case corticotrophin was used in the belief that the inflammation at the periphery of an infarct might be interfering with normal conduction

The opportunity to confirm the diagnosis of inflammation arose only in case 2, where a cellular reaction with secondary calcification was found extending across the bundle from the diseased aortic valve This reaction could well have been inhibited by corticotrophin, but, if this is what happened, it is surprising that neither cortisone 200 mg daily nor prednisone 60 mg daily eliminated the heart-block. Possibly these doses were not large enough Opportunities to make similar comparisons between the effects of corticotrophin and adrenal steroids in cases 1 and 3 have not arisen

The improvement observed in our patients may have been due not to the suppression of inflammation but to an alteration in the metabolism of the heart-muscle which was favourable to conduction and contraction Such alterations have been postulated in Cushing's syndrome (Lown et al 1955) and during therapy with corticotrophin and with cortisone (Medical Research Council and American Heart Association 1955)

Hajdu and Szent-Györgyi (1952) have shown that, in the isolated frog's heart, deoxycortone can influence contraction and the state of the muscle between contractions, probably by a modification of ionic transport across the cell membrane, but it is difficult to draw inferences about human heart-block from the results of their experiments

The only direct evidence that heart-block may be influenced by metabolic changes is the observation that it can sometimes be abolished by infusions of molar sodium lactate (Bellet et al 1955, 1956, Swash and Wallace 1956)

In the treatment of refractory cases of Stokes-Adams attacks the choice between corticotrophin therapy and infusions of molar sodium lactate may be difficult Lactate infusions probably act more quickly, which could be a decisive advantage in some cases On the other hand, corticotrophin therapy avoids the need for an intravenous infusion and the considerable risks associated with the production of an acute rise in plasma pH Only further experience with both methods can determine their relative efficacy and safety The effects of the various adrenal steroids on Stokes-Adams attacks also merit further study

Summary

Three patients with severe Stokes-Adams attacks improved strikingly within a few hours of the start of corticotrophin injections They had all failed to respond to atropine and adrenergic drugs

We are grateful to Dr K D Keele for permission to publish case 3

PINK DISEASE AFTER APPLICATION OF MERCURY OINTMENT

MARGARET E R STONEMAN
M B Manc, D C H
PÆDIATRIC REGISTRAR, EXETER CITY HOSPITAL, DEVON

SINCE Warkany and Hubbard (1948) first described the high content of mercury in the urine of many children with pink disease, there has been much speculation about its exact importance in the pathogenesis of the condition

I report here the simultaneous development of pink disease in siblings who had been exposed, for a short period before the disease began, to identical sources of mercury

Case-reports

Case 1—A girl, aged 3 years and 1 month, was the first child of healthy parents She had never been given teething-powders or any medicine other than magnesia Early in December, 1955, she became irritable and, during the next three weeks, gradually lost her appetite and began to have screaming attacks during the night She lost about 5 lb in weight during this period At the beginning of January, 1956, her fretfulness increased, and she developed incontinence of urine and fæces Her hands and feet were extremely pink She was admitted to hospital on Jan 13, 1956

On examination she was thin and fretful, with no photophobia Her hands and feet were red, and one hand was peeling She had a follicular papular rash on her trunk Her pulse-rate was 122, blood-pressure 145/90 mm Hg, and heart normal There was no sign of infection in her throat, ears, chest, or urine Her inguinal glands were slightly enlarged Tendon-reflexes were all brisk and equal on both sides

Investigations—Examination of the blood showed Hb 104% (15 4 g per 100 ml), and white cells 6200 per c mm, neutrophil polymorphs 57% (3534 per c mm), lymphocytes 42% (2604 per c mm), monocytes 1% (62 per c mm) The serum-sodium level was 288 mg per 100 ml (125 mEq per litre), potassium 19 5 mg per 100 ml (5 mEq per litre), chloride 515 mg per 100 ml (88 mEq per litre) Radiographs of long bones, epiphyses, and abdomen were normal The urine contained a trace of albumin but no cells or casts, the pH was 6 0 160 ml of urine passed in twenty-four hours contained 112 μg of mercury

The patient was discharged home on Jan 21, 1956, and subsequently made a complete recovery

Case 2—A baby, aged 13 months, brother of case 1, had never been given teething-powders or any medicine other than magnesia Early in December, 1955, he became fretful, and this was attributed to teething Three weeks later his fretfulness increased, and he became limp and unable to sit up He also started to pull out his hair He developed a rash with pink hands and feet a week later than his sister His feeding and sleeping habits were not altered He was admitted to hospital with his sister on Jan 13, 1956

On examination he was well nourished but fretful, with no photophobia He was continually pulling at his hair He was sweating profusely, although his skin was cold His hands and feet were red and cold and covered with a maculopapular rash Apart from a napkin rash, the rest of his skin was clear His pulse-rate was 148 and blood-pressure 135/80 mm Hg His heart was normal There was no sign of infection in his throat, ears, chest, or urine, but his axillary and inguinal glands were slightly enlarged on both sides His tendon-reflexes were all present but diminished, and he had general hypotonia

Investigations—Examination of his blood showed Hb 92% (13 6 g per 100 ml), white cells 10,800 per c mm, neutrophil polymorphs 78% (8424 per c mm), lymphocytes 16% (1728 per c mm), monocytes 6% (648 per c mm) Serum-chloride level 547 mg per 100 ml (93 mEq per litre) Radiographs of long bones, epiphyses, and abdomen were normal 82 ml of urine passed in twenty-four hours contained 246 μg of mercury

The patient was discharged home on Jan 21, 1956, and has since made a complete recovery

Discussion

It was clear, from the urines of these two children that they had been exposed to a copious source of mercury For a long time all attempts to trace this source were fruitless, but finally, through the efforts of Mr M P Morel, the children's family doctor, the mystery was solved On repeated questioning the mother had always denied that any ointments had been applied to her children, but many months later she remembered that, in mid-October, 1955, another doctor had supplied an ointment, subsequently identified as ung hyd ammon *B P*, to be rubbed inside the anal margin and on the perianal region of the younger child each night as treatment for a possible threadworm infection This treatment had been continued up to the time of the child's admission to hospital The elder sister was extremely jealous of her brother and had insisted that she should have similar applications These had been given with equal thoroughness

Extensive inquiries did not reveal any other source of mercury to which the children might have been exposed

Pressure of medical opinion has led to the virtual disappearance of mercury-containing teething-powders, but children may still absorb dangerous quantities of mercury exhibited in other forms The prescription of any preparation containing mercury for children in the susceptible age-group should be avoided when effective alternative treatment exists

My thanks are due to Dr F S W Brimblecombe, under whose care these patients were admitted to hospital, Mr M P Morel, F R C S, for referring the patients and for solving the mystery of the source of the mercury, and Miss Margaret M McCready, B SC, for estimating the mercury in the urine

SPONTANEOUS RUPTURE OF THE ŒSOPHAGUS AND BRONCHIAL ASTHMA

EDMUND J RATTLE
M B Lpool, D C H
MEDICAL REGISTRAR, ST CATHERINE'S HOSPITAL, BIRKENHEAD

SPONTANEOUS *rupture of the œsophagus, although rare, is being increasingly recognised during life* I report here two cases of spontaneous rupture of the œsophagus presenting with bronchial asthma within six months in a general medical unit This combination does not appear to have been reported previously

Case-reports

Case 1—A man, aged 32, an engineer by trade, was admitted to Saint Catherine's Hospital late on the night of April 25, 1957 He had had asthma since the age of 10 years He served with the R A F in the late war, both at home and abroad During this time he had little chest trouble, but since demobilisation in 1945 he had lived at home with his mother for twelve years in constant need of his isoprenaline spray

He was rehabilitated in engineering in 1956 and took a job locally at which he was happy, and he was not troubled with asthma At Easter, 1957, he had noticed ankle swelling, which subsided with rest A few days before admission he had felt more tired than usual, but he remained at work Twelve hours before admission he started with an attack of asthma, and his condition deteriorated rapidly despite the use of bronchodilating drugs He became very dyspnœic and cyanosed He complained of no pain in his chest, had no nausea, and did not vomit Cough, which was minimal, produced mucoid sputum flecked with blood An hour before admission he became stuporose

On admission he was very distressed by dyspnœa He was a big heavy man and sat propped up in bed using his accessory muscles of respiration and perspiring freely Pulse-rate 120 and temperature 102°F Expiratory rhonchi were heard throughout both sides of his chest and crepitations at both bases There was no subcutaneous emphysema of his chest wall His blood-pressure was 120/80 mm Hg His abdomen was soft and not tender

Treatment and course—He was given intravenous aminophylline and intramuscular phenobarbitone sodium, and a four-hourly course of intramuscular penicillin and streptomycin was started No improvement took place in the next two hours, by which time his temperature had risen to 103 4°F His respirations became very rapid and shallow, with definite bronchospasm, cyanosis developed, and he appeared more collapsed Oxygen and further intravenous aminophylline were administered, and intramuscular cortisone was given but without any observable effect His condition deteriorated and he died at 8 A M the following morning

Necropsy revealed bloodstained turbid stomach contents in the left pleural cavity, acute inflammation on the pleural surface of the left lower lobe, emphysema of both lungs, sticky mucus in the bronchi, stomach contents in the œsophagus and pharynx, and a linear tear 1 inch long in the lower end of the œsophagus on the left side, through which the stomach contents were leaking into the left pleural cavity There was also a large tear in the cardiac end of the stomach, and stomach contents had escaped into the peritoneal cavity There was no evidence of ulceration of either the œsophagus or the stomach No other abnormalities were found

Case 2—A spinster, aged 45, was admitted to Saint Catherine's Hospital late on the evening of Oct 22, 1957 Apart from an operation on her nasal sinuses for " catarrh " the year before, she had had no illness in her life Three and a half weeks previously she had consulted her general practitioner, who thought she was starting with influenza, and advised her to go to bed Cough and wheeziness developed, which were not relieved by cough medicines She was off her food and remained in bed Concern was felt about her condition, and after a week a physician was called in consultation He noted intense generalised expiratory bronchospasm on auscultation Bronchial asthma was diagnosed, and tab 'Franol' and 'Iso-bronchisan' together with an expectorant mixture were prescribed For the next ten days the patient remained much the same, but she got out of bed for a while each day She slept badly, and during the night she was much troubled with coughing Two days before admission her dyspnœa got worse She had no pain in her chest and at no time vomited

On admission she appeared well built and sat up in bed using her accessory muscles of respiration She was dyspnœic, tachypnœic, and slightly cyanosed Examination of her chest revealed expiratory bronchospasm throughout both sides Her temperature was normal, her pulse-rate 100, and her blood-pressure 145/80 mm Hg She had no subcutaneous emphysema of her chest wall, and nothing else abnormal was noted on clinical examination

Treatment and course—She was given intravenous aminophylline, and a course of parenteral penicillin four-hourly was started Intramuscular phenobarbitone sodium was given, and later tetracycline therapy was started She became weaker and died at 9 30 A M the following morning

Necropsy revealed very sticky mucopus in the trachea and bronchi The left pleural cavity contained bloodstained stomach contents The lungs showed a sticky purulent bronchitis There was a linear tear of the œsophagus 2 inches long immediately above the diaphragm on the left side There was no ulceration of the œsophagus or of the stomach No other abnormalities were found

Discussion

Boerhaave first recognised spontaneous rupture of the œsophagus pathologically in 1724 Many reviews of this subject have been published in the last few years (Barrett, 1946, Ware et al 1952, Moynihan 1954, Anderson 1957) and more than two hundred cases have been reported In no case has rupture of the lower end of the œsophagus been described in association with bronchial asthma

The presenting symptoms are, in most cases, sudden onset of substernal, epigastric, or abdominal pain usually preceded or accompanied by vomiting Dyspnœa, shock, and cyanosis develop later, the dyspnœa resulting from the pain or from the development of a pneumothorax or a hydrothorax The earliest sign is said to be subcutaneous emphysema (Chamberlain and Byerly 1957) and has been reported in many cases Abdominal rigidity and tenderness occur, and signs of pneumothorax, hydrothorax, or pyopneumothorax develop later Bronchospasm has not been reported

The outstanding feature of the two present cases was the complete absence of pain and vomiting (in both cases details of the illness were checked with the relations after the necropsies) In case 1 there was a long history of bronchial asthma In case 2 severe bronchospasm was associated with bronchitis following influenza in an otherwise healthy woman

The ætiology of true spontaneous rupture of the œsophagus is unknown Many of the so-called " spontaneous ruptures " of the lower end are either postemetic or secondary to œsophagitis and ulceration which may have been symptomless A sudden increase in intra-abdominal pressure appears to be the precipitating factor in all cases and is the common denominator in rupture of the lower end of the œsophagus in pregnancy or labour, or associated with defæcation, strenuous exercise or epilepsy, severe vomiting, intracranial disease, or peritoneal irritation Cough is seldom associated with rupture of the œsophagus (Anderson 1957)

It seems likely that in both these cases, rupture of the œsophagus was secondary to raised intraluminal œsophageal pressure associated with severe wheezing and coughing From the two histories bronchospasm was unlikely to have been the presenting feature of the spontaneous rupture Published discussions of the differential diagnosis of spontaneous rupture do not include bronchial asthma

It is perhaps too much to suggest that spontaneous rupture of the œsophagus should be considered in a patient with bronchial asthma who has not responded to bronchodilating drugs There should be no delay, however, in such a situation in X-raying the patient's chest if the underlying lesion is to be detected Physical signs are obscured by the loudness of the expiratory wheeze The earliest sign of spontaneous rupture of the œsophagus on radiography is loss of translucency behind the heart, due to air escaping into the mediastinal tissues Today, when timely surgical intervention combined with antibiotic therapy can be lifesaving, it seems important not to miss this condition

I wish to thank Dr A Grunberg, under whose care these patients were admitted, for permission to publish, and Miss R Rawcliffe who performed the necropsies

FRENCHAY HOSPITAL, BRISTOL

THE successful treatment of a very severe case of tetanus with antitoxin and relaxing agents and by intermittent positive-pressure respiration in the presence of many complications is reported here

Honey et al (1954) were the first to report the treatment of established tetanus with tubocurarine and intermittent positive-pressure respiration, and were followed by Lassen et al (1954, 1956), Shackleton (1954), Smith et al (1956), and Ramsay et al (1956) The historical and therapeutic background of this treatment has been well covered by them and by Ablett (1956)

Knott and Cole (1952) defined six clinical types of tetanus and suggested that the severity of the disease tends to be inversely proportional to the length of the incubation period In the case reported here it was impossible to fix the incubation period, because the patient had two operations and a preoperative cut-down blood-transfusion, at any of which the infection may have taken place No swab taken from any wound on this patient at any time showed evidence of *Clostridium tetani* The incubation period may have been as short as eight days

Knott and Cole, however, further state that a more valuable measurement in assessing prognosis is the interval between the first symptom (usually trismus) and the first generalised reflex spasm, this may be termed " the period of onset " Usually, the longer the incubation period the longer is the period of onset, but, if there is any discrepancy, the period of onset gives a better indication of the probable severity of the tetanus As a guide to prognosis they suggest the following rule if the incubation period is more than seven days and the period of onset more than two days in an otherwise healthy patient, the chance of recovery is good On the other hand, with figures less than these the prognosis becomes rapidly worse

Case-report

A not very robust woman, aged 43, had bronchiectasis in her left lower and lingular lobes and her right middle lobe, On Jan 25, 1957, she underwent a dental clearance and on Feb 4, 1957, a left basal and lingular lobectomy Her convalescence was initially uneventful, though she ran a low-grade pyrexia from the third day and had been coughing up a good deal of bloodstained sputum Seven days after the operation, in the evening of Feb 11, she had backache and dysphagia By 6 A M on Feb 12 she had hypertonicity of the muscles of her neck and upper abdomen, and by 9 A M tetanus was diagnosed At 1 P M her rigidity had increased, and soon afterwards she had the first of two ' cyanotic attacks ", probably due to difficulty in swallowing saliva and pharyngeal secretions She therefore underwent tracheotomy under general anæsthesia with thiopentone, succinylcholine, and endotracheal gas-oxygen by controlled respiration A short right-angled cuffed tube mounted on a Magill suction T-piece was inserted into the trachea, and an œsophageal tube was passed into the stomach The thoracotomy, intravenous-drip, and drainage-tube wounds were explored and debrided

Day 1 (Feb 12)

The patient was given antitetanic serum 5000 units intramuscularly and 100,000 units intravenously and penicillin 1,000,000 units intramuscularly After the tracheotomy the patient quickly recovered consciousness, and sedation with intramuscular sodium phenobarbitone gr 3 six-hourly was started She also received small doses of pethidine intravenously from time to time From this time onwards, for thirteen days, she was kept continuously relaxed with tubocurarine and her lungs were ventilated by intermittent positive-pressure respiration Feeding through the œsophageal tube was begun with 3½ oz of ' Complan ' in 15 fl oz of water two-hourly Initially, respiration was effected by manual bag-squeezing through a Waters soda-lime canister, but later that evening the patient was connected to a Mortimer respirator She was ventilated with a mixture of 5 litres of air and 2 litres of oxygen

Day 4

Tubocurarine was continued in a dosage of slightly less than 10 mg hourly The patient's temperature rose to over 101°F Catheterisation initiated a bout of twitching During the removal of the endotracheal tube for cleansing, a bronchoscope was passed Little or no sputum was aspirated, but the endoscopy provoked generalised muscle twitchings During the night the patient was ventilated by continuous manual bag-squeezing, and apart from short periods the respirator was abandoned because its use seemed to be associated with an immediate accumulation of carbon dioxide

Day 5

Radiography showed that the patient's left upper lobe had partly collapsed, therefore vigorous two-hourly physiotherapy was directed to it, and the patient continued to be turned hourly from one side to the other

Day 6

The patient's temperature rose to 103°F Her right dorsal lobe appeared to be collapsed, so she was turned on to her face for about ten minutes for physiotherapy to this lobe aided by intratracheal suction Alarming distension of her abdomen appeared, so ' Sennokot ' was given through the œsophageal tube to initiate a bowel movement

Day 8

A Radcliffe pump lent to the hospital proved, with its ready adaptability to various respiratory rates and pressures, an enormous relief to the anæsthetic staff and apparently to the patient, who settled down well on this respirator Routine radiography showed an empyema in the left side of the chest Under local analgesia an intercostal catheter was inserted and connected to an underwater seal, and air blowing from the catheter confirmed the presence of a bronchopleural fistula Clinical examination suggested that the right lower lobe was collapsed, so, while the endotracheal tube was removed for cleansing, the vocal cords were sprayed with lignocaine 4%, and the patient was bronchoscoped This procedure made her cyanosed, and she required pure oxygen for half an hour afterwards until her pulse-rate settled down again During the evening her pulse-rate suddenly increased to 180 and an electrocardiogram showed auricular tachycardia Aminophyllin 0 48 g was given intravenously to relieve bronchospasm Acute paralytic ileus developed The distension of the bowel pushed the liver up against the flaccid right diaphragm and aggravated the collapse in the right lower lobe Much " coffee-grounds " fluid was aspirated through the œsophageal tube The patient was deeply unconscious, her hands became cyanosed, and her systolic bloodpressure fell to 50 mm Hg, indicating peripheral circulatory failure Her temperature rose to 104°F

Day 9

In the early hours the patient was apparently moribund, but a noradrenaline drip 4 mg per 500 ml of physiological saline solution was started at 60 drops a minute, and in the next twelve hours the patient improved dramatically 2 pints of blood was given Her temperature reached its peak of 106°F by the early morning, and cooling with wet sheets and electric fans was started

Day 10

The noradrenaline drip was discontinued after twenty-four hours, during which she had had 44 mg of the drug The dosage of relaxant during this period of severe illness was the lowest so far required in a day The paralytic ileus cleared up, and there was a general improvement in her lungs

Day 11

She began taking very small quantities of fluids by mouth Owing to her exhausted condition she required only 70 mg of tubocurarine in the twenty-four hours

Day 12

Her improvement was maintained Vigorous physiotherapy to her chest was continued. She showed signs of resisting the action of the Radcliffe pump, so, when the last dose of tubarine was wearing off, she was taken off the respirator for one to two minutes and encouraged to respire unaided She cooperated well in this, so we withdrew the relaxant, but after four hours without tubocurarine she had a major tetanic spasm

Day 13

Abdominal distension recurred, but gastric suction and intravenous dextrose and saline solution prevented ileus With the onset of distension the patient's right lower lobe collapsed again Her temperature rose to 102°F

Day 14

She received her last regular dose of tubocurarine After a second test withdrawal of relaxant there was no convulsion By the evening she could, with difficulty, open her eyes At this stage she still had hypertonicity and pain in the neck and intercostal muscles, and to overcome this she was given mephenesin 0 5 g two-hourly by mouth

Day 16

She breathed spontaneously for four hours The mephenesin was reduced to 0 25 g three-hourly, but neck rigidity was still severe, and the onset of increasing difficulty in inflating the chest caused us to revert to two-hourly dosage again, with good result Attempts to re-educate the swallowing reflex were made, but head retraction, neck rigidity, and the œsophageal tube hindered progress Attempts at swallowing caused saliva to appear in the tracheotomy wound

Day 17

A sudden increase in sputum necessitated bronchoscopy Since the patient's hæmoglobin was only 71%, she was given a transfusion of 2 pints of blood She was rather more restless and uncooperative, and we feared lest her cerebral cortex had suffered in the early cyanotic attacks, and we wondered whether we had been labouring so hard merely to keep alive a decerebrate

Day 18

The patient still required machine ventilation at times, as and when her own spontaneous respiration became rapid and inadequate

Day 19

She was still producing large amounts of sputum and was easily exhausted and worried by prolonged periods off the Radcliffe pump She would pass readily into tranquil sleep immediately after the start of artificial ventilation She was not easily roused to cooperation, and since she had had gr 197 of intramuscular phenobarbitone in twenty days the daily dose of this drug was immediately halved

Day 20

Lobar and segmental collapse still occurred rapidly and frequently The two-hourly regime of turning and physiotherapy was maintained The patient's spontaneous respiration was 40–44 a minute The œsophageal tube was removed after several successful attempts to swallow with the tube in place

Day 21

When the patient was breathing spontaneously through her tracheotomy, lack of humidification of inspired air seriously added to her difficulty in expectorating A Walley humidifier (Walley 1956) satisfactorily overcame this difficulty in a few hours This was the sixth day following the withdrawal of tubocurarine, and, though her tetanus was clearly cured, we were anxious at her continued drowsiness The appearance of athetotic movements aggravated our suspicions that she had had cerebral hypoxia Her appearance at this time is shown in the illustration, with the Walley humidifier in use All sedatives were discontinued this day The removal of the œsophageal tube seemed to have been premature, because further attempts at swallowing were not so successful as at first A sound sleep was ensured by putting the patient back on the Radcliffe pump for the night

Patient on 21st day wearing Walley humidifier

Day 22

The patient coughed more strongly now and produced sputum unaided

Day 23

She was still not swallowing sufficient fluids to maintain hydration and was therefore given two pints of $N/5$ dextrose and saline solution intravenously Her lungs were very much drier, aerating well at all areas Her mental state had also much improved She showed animated enjoyment of a radio programme which she heard through earphones She asked by signs for tea and successfully swallowed semi-solids

Day 25

She regained control of her bowels

Day 26

She recognised all the relations who visited her She slept throughout the night without the Radcliffe pump, which was not used again One of our difficulties at this stage was to determine when the swallowing reflex had recovered sufficiently to enable us safely to substitute for the cuffed tracheotomy tube a plain silver tube The cuffed tube seemed to accentuate the dysphagia, but the presence of food debris on top of the cuff appeared to us to be a definite contraindication to removal of the tube

Day 27

When the cuffed tracheotomy tube was temporarily removed on day 27 and the tracheostomy was occluded, the patient was able to phonate, repeating her name again and again She later confessed that her great pleasure at this achievement was because she thought she was never going to speak again

Day 28

She had partly regained control of micturition

Day 36

The tracheotomy tube was finally removed and the tracheotomy sinus allowed to close by granulation

Day 41

Skin was grafted on to her right foot under general anæsthesia because she had sustained a hot-water-bottle burn in the early days of her illness

May 22

The patient was discharged, having made a complete physical and mental recovery

Discussion

Prognosis

Based on the criteria of Knott and Cole (1952) prognosis seemed very poor The fulminating onset, the residual bronchiectasis, and the recent resection of lung were complicating factors Later she had an empyema and a bronchopleural fistula At one time or other almost every pulmonary segment collapsed A regime of antibiotics, three-hourly (and sometimes two-hourly) physiotherapy, postural drainage, bronchoscopy, and regular intratracheal suction prevented permanent atelectasis

Alimentary

Nutrition and hydration were maintained principally with complan $3^{1}/_{2}$ oz in 15 fluid oz of water three-hourly This volume was modified from time to time in the light of the patient's general condition

Relaxants

Tubocurarine was chosen as the relaxant because of its lack of side-effects, its length of action, its ease of administration, and its successful use in previously published cases Relaxation was carried to a point where the respiratory muscles were sufficiently atonic to permit the efficient exchange of gas by mechanical ventilation of the lungs The patient could often flex her wrists in spite of otherwise adequate curarisation, and we used this movement during her more lucid moments as a signal whereby she was able to respond to questions, using one wrist movement to answer " yes ", and the other " no "

Major tetanic convulsions were suppressed by curarisation, and none occurred from the onset until the twelfth day, when she was permitted to emerge from paralysis as a test of cure Generalised twitchings occurred when carbon dioxide accumulated, but these could be corrected, and it was not thought necessary to abolish them entirely Tubocurarine was given at all times through a Mitchell intravenous needle During the difficult transition period between complete relaxation with tubocurarine and the restoration of normal muscle tone, mephenesin was of great value in overcoming the painful hypertonicity of the neck and intercostal muscles

Respirators

After an initial period of manual ventilation the patient was connected to the Mortimer respirator on the evening of the first day Within forty-eight hours we had each independently decided that she was uncomfortable on this type of respirator Carbon dioxide accumulated quickly, but in our inexperience we may have contributed to this by giving inadequate doses of curare to allow the respirator to work effectively It was clear, however, that a smaller dose of relaxant was satisfactory when either manual ventilation or the Radcliffe pump was in use

The Radcliffe pump proved entirely reliable and easy to operate and had a conveniently wide range of speeds In the model lent by the manufacturers the suggested temperature setting of the thermostat in the humidifier produced droplets of water in the polyethylene tubes, so the setting was twice reduced, and finally the humidifier was used only intermittently Opinions varied on the desirability of using a negative phase in the respiratory cycle, and after a few days' trial it was discontinued, without apparent detriment to the patient

Inflation pressures varied between 18 and 25 cm of water The accumulation of carbon dioxide was indicated clearly and consistently by a sudden sharp rise in blood-pressure from the average of 120/80 mm Hg to 160/100 mm Hg or more, within two minutes of this sign the patient would begin to sweat profusely and then to twitch all over The soda lime was changed when on bag ventilation, or a further dose of tubocurarine allowed the respiratory muscles to relax sufficiently to clear the accumulation

For ventilation a mixture of air and oxygen was used principally (5 litres of air and 1 litre of oxygen), but at times it became necessary to use pure oxygen Nitrous oxide was not used at all, because Lassen et al (1956) reported severe depression of the bone-marrow after its prolonged use

Medication

Other workers have found chlorpromazine of value in treating milder tetanus Among its attributes is the freedom from excessive pharyngeal and bronchial secretions, which are common in tetanus Owing to gross infection in the present case we felt that the danger of liver damage contraindicated its use

Sedation was achieved initially with intramuscular sodium phenobarbitone gr 3 six-hourly and pethidine, but as the patient deteriorated she required progressively less sedation

Blood Chemistry

Estimations varied surprisingly little from the normal figures There was a tendency towards acidosis, and transient hypokalæmia came on during the gastrointestinal upsets All the estimations returned to normal after the resumption of spontaneous respiration

Humidification

During the first seven days, when ventilation was effected either by the Mortimer respirator or by manual bag-squeezing, the soda-lime canister acted as a very efficient humidifier While the Radcliffe pump was in use, the humidifier incorporated in the machine was used intermittently Humidification became a problem only when the patient was breathing spontaneously through the tracheotomy tube, and then the crusting of the secretions caused a deterioration in the condition of her lungs, which was rectified by the use of a Walley humidifier

Summary

Severe postoperative tetanus, complicated by bronchiectasis, empyema, bronchopleural fistula, and peripheral circulatory failure, was successfully treated with antitoxin, antibiotics, muscle relaxants, and intermittent positive-pressure respiration

The patient's complete recovery involved the full-time attention of anæsthetists for three weeks, and at all times the exceptional skill and enthusiasm of the nurses and physiotherapists

We wish to thank numerous friends and colleagues for their help and advice, especially Dr A Crampton Smith, of the Oxford respiratory unit, and Mr H G East managing director of East and Co , Oxford, from whom we hired the Radcliffe pump

Preliminary Communication

THE ACTION OF QUINIDINE INTERPRETED FROM INTRACELLULAR POTENTIALS OF SINGLE CARDIAC FIBRES

THE mode of action of quinidine has long presented a puzzling paradox. Lewis, Drury, Iliescu, and Wedd[1] originally claimed that quinidine prolonged the absolute refractory period of the dog's atrium, and, since the drug was also antifibrillatory, they considered that the evidence supported their view that fibrillation involved a circular sequence of excitation. Subsequently Love,[2] using a more precise method of measurement, found that the absolute refractory period was not, after all, prolonged by quinidine, but was sometimes shortened. The absolute refractory period of cardiac muscle is known to be approximately synchronous with the duration of the action potential,[3,4] and the latter also was shown not to be prolonged by quinidine.[5] The problem remained to explain how, when the absolute refractory period (i.e., the shortest interval after a stimulus at which a local response could be elicited by a second stimulus) was unchanged or shortened, quinidine nevertheless reduced the "effective refractory period", thus lowering the frequency at which propagated impulses could be conducted.

Recently developed techniques now enable more precise information to be obtained about the electrical activity of single cardiac fibres.

Fine capillary pipettes can be drawn with a diameter of less than 0.5 μ at the tip, and, filled with strong KCl solution, can be introduced into single cells to record potentials as efficiently as metal electrodes. When a microelectrode penetrates the membrane of a single atrial fibre, a negative potential of −75 mV is immediately recorded (the resting potential); during activity the potential swings rapidly positive to cross the original base-line and become positive inside the fibre relative to the outside by about +24 mV (the "overshoot"). The total rising phase takes about 3.0 msec. at 31°C, hence the average rate of rise is $\frac{75+24}{3.0}$=33 V per sec. The membrance then repolarises more slowly to its original value of −75 mV, reaching the half-way point in about 60 msec.

Simultaneous measurements of contraction, conduction velocity, and intracellular potential have been made in isolated rabbit atria in the presence of a wide range of concentrations of quinidine. The measurement of contractions permitted an independent estimate of toxicity, and it was found that concentrations of quinidine up to 10 mg. per litre did not reduce contraction by more than a quarter, usually by less. This agreed well with the direct measurements of serum-quinidine levels in man by Sokolow and Edgar,[6] who found that, in patients in whom atrial fibrillation was successfuly arrested, 75% of the levels were between 4 and 9 mg. per litre.

In the present experiments it was found that at concentrations of 10 mg. per litre or less there was no fall in the resting potential, and at much higher concentrations there was a reduction of only 2 or 3 mV. It was concluded, therefore, that the action of quinidine cannot be due to a change in resting potential. Again, at 10 mg. per litre or less, quinidine did not prolong the half-time for repolarisation and sometimes shortened it—which explains the absence of any change in absolute refractory period. The terminal phase of repolarisation was, however, prolonged (see below). In contrast, even at concentrations of 1–5 mg. per litre there was a great reduction in the rate of rise of the action potential and in conduction velocity. The height of the "overshoot" was also diminished.

These observations provide an explanation for the prolongation of the effective refractory period by quinidine in the absence of a change in the absolute refractory period.

It has been established[7,8] that a second propagated action potential cannot be elicited from cardiac muscle until the phase of repolarisation has proceeded to about two-thirds of the full resting potential—i.e., until the membrane has again become negative to about −50 mV in atrial muscle. A local non-propagated response can be obtained a little earlier, when the potential has reached only −42 mV; the absolute refractory period is thus a little shorter than the effective refractory period. In a normal atrium the duration of the terminal phase of repolarisation is consequently of no importance in determining the effective refractory period, because a propagated response can occur when the membrane has been repolarised to only −50 mV.

For a propagated response to occur, a certain minimum rate of rise of the depolarisation phase of the action potential is necessary, to overtake the process of accommodation. If the rate of rise is very slow, no propagated impulse can develop. It has been shown that the rate of rise is a function of the level of the potential of the membrane at which the action potential "takes off".[7,8] If a stimulus is introduced when the membrane is repolarised to −65 mV, the action potential takes off with a rate of rise much faster than if the stimulus occurs when repolarisation has proceeded only to −55 mV. As already stated, in a normal atrium the critical rate of rise for propagation can occur when the response takes off at about −50 mV. At −45 mV a local response can still occur, but the rate of rise is insufficient for propagation.

In the presence of quinidine the rate of rise itself was greatly reduced. The membrane had therefore to repolarise further before the critical take-off point was reached at which the rate of rise was fast enough for propagation. The duration of the terminal phase of repolarisation, normally unimportant, thus became significant in determining the effective refractory period. The absolute refractory period was unchanged, because the duration of the half-time for repolarisation was not prolonged by quinidine, and a local response could still occur at the normal point. But the rate of rise was so depressed that it was inadequate for propagation until repolarisation had proceeded much further than normal. The effective refractory period could, in fact, exceed the total duration of the action potential in the presence of quinidine. At high concentrations of quinidine the atria became totally inexcitable, although there was no significant fall in resting potential—i.e., the effective refractory period had become infinite, even though repolarisation was complete.

It is concluded that quinidine acts by affecting the phase of depolarisation, without necessarily prolonging the duration of the phase of repolarisation.

Medical Societies

ROYAL SOCIETY OF MEDICINE

The Physician's Obligation to Society

THE *Section of Medicine met on* April 22 with Dr W A BOURNE, the president, in the chair

Looking back on the great demographic transformation which had taken place since 1750, Dr FFRANGCON ROBERTS described it as a unique event *in the history of* the human race which could never happen again To this change from high birth and death rates to low birth and death rates clinical medicine had contributed very little until the beginning of the 1914–18 war The main factors in this transformation had been the increase in national wealth and productivity that sprang from industrialisation, the ampler food-supplies generated by the agrarian revolution, and the general adoption of birth control Medicine did come into it, however, by taking part in the philanthropic movement of the 18th century and then in the important public-health measures of the 19th century Finally the present century had seen the harnessing of medicine to science and the doctor's involvement not only in curative work but also in social medicine He also found himself bound up in commerce, where advances in medicine, we must admit, largely resided

Thus, the doctor must now share in activities never dreamt of by his predecessors How had his obligations to society changed? Basically, not at all He still had his obligation to the individuals of whom society was composed, and since the end of the 18th century he owed an obligation to society to benefit individuals indirectly by improving social environment These duties were not so straightforward as they seemed, for doctors must consider the remote consequences of their actions—overpopulation, the ageing of the population, and a change in the balance of the sexes The conquest of malaria and yellow fever had been a triumph, but medicine could not advance further than food-supply Medicine was threatening to intensify the operation of the malthusian law and had indeed done so in some places This was a social and economic question, the doctor could only bring to bear his expert knowledge on contraception when he was asked to do so The ageing of the population brought a lot of unhappiness with it Again, the doctor's obligation, in Dr Ffrangcon Roberts' estimate, was limited to medical action, the social consequences as such were not his concern By the year 2000 England and Wales would contain 350,000 more marriageable men than women This was due to the saving of the lives of baby boys who, at birth, numbered 106 to every 100 baby girls At the other end of the scale lay the much greater capacity of old women to resist mortality, at age 60 and over, women would outnumber men by *2,000,000* Civilisation must therefore face the prospect of a world of compulsory bachelors being looked after by *widowed mothers*

The creation of the perfect environment was not the success some people *had hoped for* Neuroses in new housing estates and towns were three or four times commoner than in the old situations People became unhappy despite all efforts to make them happy Every stage in reducing mortality brought fresh difficulties we created problems as fast as we solved them

Dr E R CULLINAN interpreted the discussion's title as " to treat patients ", and what the patient wanted was to be cured with the least delay and discomfort, to get out of hospital quickly, to be told where he stood, and to get back as soon as possible to his usual life Only the profession could maintain the standard of the care it provided (its employers in the National Health Service could not do so), but to maintain the background he had learned in the teaching hospital the practitioner must be allowed time to do his work properly under good conditions

One of the most refreshing things in a teaching hospital was the diversity of interest among its staff One physician might be concerned only with the treatment of the sick, another with the study of disease for its own sake each must respect the other and they mostly did Some physicians combined treatment and research, and it was important that they should be clear at all times which they were doing—and that the patient should be clear as well Sticking needles and catheters into the patients in guise of treatment when what was done was really in search of knowledge seemed to Dr Cullinan very near to common assault

One of the patient's main needs was the knowledge and courage to adjust his world to his disability The cleavage between psychologists and physicians was still too wide, and it was clear that a sharp separation between organic and functional illness was no longer tenable All illness had some emotional content and all doctors were capable of listening to the patient's story, allaying anxiety if possible, helping him to adjust, and doing everything possible to see he had all necessary aid This was ordinary good doctoring The patient in hospital should be credited with intelligence and not regarded as an object or a disease (" the appendix in number 6 ") It should be explained to him that nurses and students were learning, which was why there was something always being done, such as the eternal smoothing of bedclothes Everything possible should be done to forestall the plea " I was told nothing "

When the patient left hospital his general practitioner should know all about him before he got home If he was not fit enough to go home, it was not just enough to say would you like to go to a convalescent home or to an old people's home? Did consultants, practitioners, and students know the labyrinthine network of ways in which the patient could be helped—the realm of the State, the local authority, the voluntary bodies? Could anything be done under National Health Insurance, or by the Assistance Board, the Ministry of Labour, or the local authority's many services? And could the patient benefit from any of the help offered by one of the many voluntary bodies? The patient could get into a sort of no-man's-land between different bodies, and the general practitioner should know what was happening and act as a sort of " humane umpire " all the time *In all this systemisation,* he might be the only remaining impartial adviser, bodily and even spiritually throughout the patient's life

Dr R R BOMFORD emphasised the physician's obligation to deal with the whole person and the total disability We often dealt relatively well with the patient's physical disease, but we made a mess of treating the patient as a person Dr Charles Newman, in his book, *The Evolution of Medical Education in the Nineteenth Century,*[1] had suggested that the new growing-point of medicine would be the understanding and control of the mind and of the mental aspects of all diseases Dr Bomford was prepared to argue that Freud had made the greatest contribution to clinical medicine in the past hundred years, because he had introduced a new clinical method—listening to the

Safety in Prostatectomy

There have been three phases in the short but eventful history of prostatectomy On Dec 1, 1900, Freyer performed his first transvesical operation[1] He was not without his forerunners[2-4], but he was the first to prove beyond doubt that benign enlargement of the prostate constituted a surgical challenge He was soon joined in the fray by other pioneers, such as Rutherford Morison[5] and Thomson-Walker[6] in this country and Judd[7] and Young[8] in America, and by the end of the 1914–18 war the soundness of the operation was firmly established As is the common fate of bold surgical ventures, there followed a period of comparative stagnation and even of smugness The masters consolidated their technique, their teaching spread, the operation rapidly gained in popularity, but the mortality and morbidity rates remained unchanged For a new and still almost experimental form of surgery both rates were gratifyingly low, but, considering that the operation was undertaken for an essentially benign condition, these rates were not inconsiderable In the inauguration of the third phase Harris[9] played a decisive part His technical innovations were by no means dramatic, but he set out the details of his operation with unsurpassed clarity his step-by-step account of the management of patients could be followed by any busy general surgeon, and, most important perhaps, he turned his own, and he drew his colleagues', attention from the theatre to the ward By careful pre- and post-operative care prostatectomy was to become safe as well as sound

It has been said with much justice that " more patients die by the catheter than by the prostatectomy "[10], and it is therefore right that the catheter should have become the crux of surgical inquiry and dispute McEachern and his colleagues[11] at the Royal Adelaide Hospital advocate urethral catheterisation After decompression the catheter is tied in In cases of acute retention operation follows decompression at any convenient time within thirty-six hours, " a faster tempo than this is considered to be unsound practice, because there are too many important associated conditions which may be missed if the journey from receiving room to theatre is too short " Chronic retention is relieved by slow decompression, and if the blood-urea-nitrogen is over 40 mg per 100 ml—especially if this is manifest by uræmic symptoms—catheter drainage is continued under chemotherapeutic cover for seven to ten days McEachern claims that the dividends of this policy, both in lessened mortality and in shortened convalescence, have been gratifying, and statistical support for this claim is not wanting On the other hand, surgeons who prefer the suprapubic route of decompression, and those who reject any form of catheterisation as an unnecessary evil, can point to results which are at least equally good[12 13] and many would regard McEachern's management of chronic retention as retrograde " Slow decompression," Wells[14] said recently, " a sine-qua-non of recent days, is now, I presume, defunct It was based upon the theory that rapid decompression caused hæmorrhage and suppression of urine, complications now recognised as due to trauma and infection, or to electrolyte imbalance " Wells also criticised the facile acceptance of infection as an inevitable concomitant of stasis Autogenous infection of the bladder from the kidneys is certainly rare, and stasis per se does not lead to infection Only when stagnant urine is contaminated by catheter or by cystoscope does it become (and remain) infected With many practical obstacles barring the way to routine immediate prostatectomy, the risk of preliminary drainage may have to be accepted, but it remains a grave risk

Urethral catheterisation can lead to bladder infection in at least three different ways Organisms can be introduced by the catheter itself, and those who see this as the main danger prefer the indwelling catheter to repeated catheterisation Others picture the formation of a thin film of " culture-medium " between the catheter and the urethral wall—a broad highway rather than a free passage for organisms—and they recommend withdrawal of the catheter as soon as the bladder has been emptied Finally, the importance of intraluminal spread is shown by the reduced incidence of postoperative infection with the aseptic closed-bladder drainage[15 16] The provenance of the organisms is equally obscure Autogenous sources—the bowel and the traumatised prostatic bed—may account for some infections, but more and more evidence favours true cross-infection[17]

Unfortunately, catheterisation is still undertaken for no good reason far too often Acute retention can often be relieved by more homely and less dangerous methods, and to pass a catheter merely to measure exactly the amount of residual urine is the essence of meddlesome surgery

Abuse of antibiotic cover is so common that it would be surprising if this branch of surgery were exempt, the increasing proportion of resistant strains of *Escherichia coli* and *Staphylococcus aureus* isolated from specimens of urine after catheterisation need cause no surprise

In their operative technique McEachern and his colleagues differ little from surgeons in this country They approach the prostate by Millin's retropubic route[18] and follow Harris's method in the enucleation of the gland Like others, they have found chemotherapy no substitute for ligation of the vasa deferentia A rise in the incidence of osteitis pubis cast a cloud over the early history of Millin's operation, but McEachern

The claims of patients who seek operation for cosmetic reasons to be considered as truly in need of medical care are fully discussed To Gillies, a patient who needs a face-lift is a patient in need of medical help, and he operates on the mind through the face On the question of choice of operation for breast reduction, Gillies rightly draws attention to the advantages of the free graft of the nipple in elderly patients who need a major reduction Most patients who want a breast reduction are middle-aged, and not interested in two-stage procedures, they want a substantial reduction and an attractive breast form in one operation, and for most of them the free-graft method of Thorek is probably the best available today

A chapter is included on the difficult and controversial question of the surgery of sex conversion Here it is impossible to be dogmatic, partly because there is no generally accepted definition of sex There are different opinions about the appropriateness of operating on the external genitalia of people who ask for such operations Transvestites of either sex may be unsatisfactory patients, but it is unreasonable to deny that they are largely a medical responsibility, and Gillies has courageously accepted an aspect of this responsibility Valuable evidence can be expected from the later psychological outcome of his operations At the moment it seems that the adjustment to life of the "women" who are converted into "men" is better, in the sense of their becoming more stable and more reliable, than is the conversion of "men", mostly transvestites with homosexual tendencies, into "women"

Gillies has been specially fortunate in his co-author, Dr Millard, who devoted himself wholeheartedly to the enormous task of producing these concentrated volumes His own contributions to surgery are growing, and the merit of his work in Florida is widely recognised The book includes a chapter on anæsthesia by Dr Ivan Magill, without whose help in devising the necessary anæsthetic techniques for jaw and facial operations the specialty would never have developed as profitably as it has It is fitting that he should contribute to a book of historic importance, which must rank as one of the major surgical works in English of this century

The Doctor, His Patient, and the Illness

MICHAEL BALINT, M D, consulting psychiatrist, Tavistock Clinic London Pitman Medical Publishing Co 1957 Pp 343 40*s*

IN some medical schools, teaching about mental and emotional illness is still limited to a few lectures and to demonstrations of spectacular cases (Huntington's chorea, for example) Dr Balint rightly says that students are told to treat the whole patient, but are given little or no indication how to do so, which is unfortunate because much of general practice is concerned with emotional illness The untrained doctor may do harm as Dr Bomford observed at the meeting we report on p 944, the doctor-patient relationship may sometimes be pathogenic and very occasionally lethal Reassurance is often useless, and avuncular common-sense advice "is as limited and crude a tool as are carving-knife and screwdriver in surgery" On the other hand, there are good reasons for the deficiency most students are probably too immature to grapple with their patients' emotional difficulties, and there is little real knowledge about the treatment of whole patients that students can be taught

Dr Balint has organised seminars at which a group of family doctors and a psychiatrist discuss patients, their objects are less to help particular patients than to train themselves in psychotherapy and to research into the illnesses encountered and the treatments needed The group training can also help the doctor to achieve the personality change he usually needs, according to Dr Balint, to be a successful psychotherapist, for his personality determines his response to his patient and the treatment he gives The family doctor is well placed for such work Unlike the specialist, he sees the whole patient, whom he meets in many ways—as physician, obstetrician, psychotherapist, and family friend He sees the patient early in the illness when the prospects for preventive work are best, and unlike the specialist he is always available Most who have tried it find it a heavy responsibility but richly rewarding

Dr Balint's book is based on material gathered at these seminars It is really several books in one—an inquiry into the effect of the doctor on the patient (what he calls the pharmacology of the doctor as a drug), a plea for training in psychotherapy for suitable family doctors, a valuable source-book for anyone seeking to organise similar seminars, and a call for research into the pathology and treatment of the whole patient—which can be done only by general practitioners, and perhaps best through the type of meetings that Dr Balint describes

Everyone will take issue with some of his ideas, but there is so crying a need for research and training on the lines he advocates, and his book is so eloquent and modest a plea, that we hope it will be read by very many family doctors, psychiatrists, and teachers of medicine

Surgical Management of Pulmonary Tuberculosis

Editor JOHN D STEELE, M D, associate clinical professor of surgery, University of California School of Medicine Springfield, Ill Charles C Thomas Oxford Blackwell Scientific Publications 1957 Pp 213 72*s*

THIS monograph is dedicated to the memory of John Alexander "with the affection, admiration and gratitude" of the thoracic surgeons he trained Similar monographs on other aspects of thoracic surgery will follow The surgery of pulmonary tuberculosis was Alexander's first interest—and the book on which he was working at the time of his death was to have had a similar title To produce a book which is a worthy memorial to a great figure is, however, far from easy and imposes certain limitations on editor and contributors which make repetition and stodginess hard to avoid In the circumstances original thought is scarcely to be expected and the authors have largely resorted to a historical review supplemented by a description of technique and an assessment of results The chief merit of the work, therefore, is as a historical document and in this respect its painstaking assiduity gives it a high standard It is beautifully produced and the illustrations and documentation are impeccable

In the future the book will no doubt be regarded as a monument to the era when thoracic surgery in tuberculosis was feeling its way towards the simple and effective solution ultimately provided by chemotherapy and resection The conviction grows in the reader's mind that such procedures as cavernostomy, plombage, even thoracoplasty, are almost bygones, mainly because of chemotherapy, and it is to the credit of the editor that he has included a comprehensive review of chemotherapy, so marking the settled position it has achieved in tuberculosis treatment

Alexander, one of the first to specialise exclusively in thoracic surgery, had a great influence on its development in the United States, and it is fitting that his merit should receive this unique tribute

---

Current Therapy (Philadelphia and London W B Saunders 1958 Pp 781 84*s*)—Prof Howard Conn's annual is a little bigger and dearer this year, but it is a good investment for any hospital Its principal user will probably be the houseman who wants to know quickly the modern treatment for some emergency or some condition that is uncommon or out of his experience It would doubtless be impossible to compile a book of this sort to please everyone, but there is little here to quarrel with Some eyebrows will rise at the injunction to prescribe dihydrostreptomycin 4 g daily for 6–8 weeks in endocarditis, and at the choice of propylthiouracil in thyrotoxicosis

An International Symposium on Aldosterone (London J & A Churchill 1958 Pp 225 40*s*)—It is four years since aldosterone, the only adrenal hormone which seems free from pituitary control and plays a direct part in homœostasis, was isolated in crystalline form Last June the Clinique Therapeutique of the University of Geneva organised a symposium, under the chairmanship of Prof R S Mach, and attended by European and North American workers, the proceedings are here edited by Dr Alex F Muller and Miss Cecilia M O Connor

Safety in Prostatectomy

THERE have been three phases in the short but eventful history of prostatectomy On Dec 1, 1900, FREYER performed his first transvesical operation [1] He was not without his forerunners [2-4], but he was the first to prove beyond doubt that benign enlargement of the prostate constituted a surgical challenge He was soon joined in the fray by other pioneers, such as RUTHERFORD MORISON [5] and THOMSON-WALKER [6] in this country and JUDD [7] and YOUNG [8] in America, and by the end of the 1914–18 war the soundness of the operation was firmly established As is the common fate of bold surgical ventures, there followed a period of comparative stagnation and even of smugness The masters consolidated their technique, their teaching spread, the operation rapidly gained in popularity, but the mortality and morbidity rates remained unchanged For a new and still almost experimental form of surgery both rates were gratifyingly low, but, considering that the operation was undertaken for an essentially benign condition, these rates were not inconsiderable In the inauguration of the third phase HARRIS [9] played a decisive part His technical innovations were by no means dramatic, but he set out the details of his operation with unsurpassed clarity his step-by-step account of the management of patients could be followed by any busy general surgeon, and, most important perhaps, he turned his own, and he drew his colleagues', attention from the theatre to the ward By careful pre- and post-operative care prostatectomy was to become safe as well as sound

It has been said with much justice that " more patients die by the catheter than by the prostatectomy " [10], and it is therefore right that the catheter should have become the crux of surgical inquiry and dispute McEACHERN and his colleagues [11] at the Royal Adelaide Hospital advocate urethral catheterisation After decompression the catheter is tied in In cases of acute retention operation follows decompression at any convenient time within thirty-six hours, " a faster tempo than this is considered to be unsound practice, because there are too many important associated conditions which may be missed if the journey from receiving room to theatre is too short " Chronic retention is relieved by slow decompression, and if the blood-urea-nitrogen is over 40 mg per 100 ml —especially if this is manifest by uræmic symptoms—catheter drainage is continued under chemotherapeutic cover for seven to ten days McEACHERN claims that the dividends of this policy, both in lessened mortality and in shortened convalescence, have been gratifying, and statistical support for this claim is not wanting On the other hand, surgeons who prefer the suprapubic route of decompression, and those who reject any form of catheterisation as an unnecessary evil, can point to results which are at least equally good [12,13] and many would regard McEACHERN's management of chronic retention as retrograde " Slow decompression," WELLS [14] said recently, " a sine-qua-non of recent days, is now, I presume, defunct It was based upon the theory that rapid decompression caused hæmorrhage and suppression of urine, complications now recognised as due to trauma and infection, or to electrolyte imbalance " WELLS also criticised the facile acceptance of infection as an inevitable concomitant of stasis Autogenous infection of the bladder from the kidneys is certainly rare, and stasis per se does not lead to infection Only when stagnant urine is contaminated by catheter or by cystoscope does it become (and remain) infected With many practical obstacles barring the way to routine immediate prostatectomy, the risk of preliminary drainage may have to be accepted, but it remains a grave risk

Urethral catheterisation can lead to bladder infection in at least three different ways Organisms can be introduced by the catheter itself, and those who see this as the main danger prefer the indwelling catheter to repeated catheterisation Others picture the formation of a thin film of " culture-medium " between the catheter and the urethral wall—a broad highway rather than a free passage for organisms—and they recommend withdrawal of the catheter as soon as the bladder has been emptied Finally, the importance of intraluminal spread is shown by the reduced incidence of postoperative infection with the aseptic closed-bladder drainage [15,16] The provenance of the organisms is equally obscure Autogenous sources—the bowel and the traumatised prostatic bed—may account for some infections, but more and more evidence favours true cross-infection.[17]

Unfortunately, catheterisation is still undertaken for no good reason far too often Acute retention can often be relieved by more homely and less dangerous methods, and to pass a catheter merely to measure exactly the amount of residual urine is the essence of meddlesome surgery

Abuse of antibiotic cover is so common that it would be surprising if this branch of surgery were exempt, the increasing proportion of resistant strains of *Escherichia coli* and *Staphylococcus aureus* isolated from specimens of urine after catheterisation need cause no surprise

In their operative technique McEACHERN and his colleagues differ little from surgeons in this country They approach the prostate by MILLIN's retropubic route [18] and follow HARRIS's method in the enucleation of the gland Like others, they have found chemotherapy no substitute for ligation of the vasa deferentia A rise in the incidence of osteitis pubis cast a cloud over the early history of MILLIN's operation, but McEACHERN

The claims of patients who seek operation for cosmetic reasons to be considered as truly in need of medical care are fully discussed. To Gillies, a patient who needs a face-lift is a patient in need of medical help, and he operates on the mind through the face. On the question of choice of operation for breast reduction, Gillies rightly draws attention to the advantages of the free graft of the nipple in elderly patients who need a major reduction. Most patients who want a breast reduction are middle-aged, and not interested in two-stage procedures, they want a substantial reduction and an attractive breast form in one operation, and for most of them the free-graft method of Thorek is probably the best available today.

A chapter is included on the difficult and controversial question of the surgery of sex conversion. Here it is impossible to be dogmatic, partly because there is no generally accepted definition of sex. There are different opinions about the appropriateness of operating on the external genitalia of people who ask for such operations. Transvestites of either sex may be unsatisfactory patients, but it is unreasonable to deny that they are largely a medical responsibility, and Gillies has courageously accepted an aspect of this responsibility. Valuable evidence can be expected from the later psychological outcome of his operations. At the moment it seems that the adjustment to life of the "women" who are converted into "men" is better, in the sense of their becoming more stable and more reliable, than is the conversion of "men", mostly transvestites with homosexual tendencies, into "women".

Gillies has been specially fortunate in his co-author, Dr Millard, who devoted himself wholeheartedly to the enormous task of producing these concentrated volumes. His own contributions to surgery are growing, and the merit of his work in Florida is widely recognised. The book includes a chapter on anæsthesia by Dr Ivan Magill, without whose help in devising the necessary anæsthetic techniques for jaw and facial operations the specialty would never have developed as profitably as it has. It is fitting that he should contribute to a book of historic importance, which must rank as one of the major surgical works in English of this century.

The Doctor, His Patient, and the Illness

MICHAEL BALINT, M D, consulting psychiatrist, Tavistock Clinic. London Pitman Medical Publishing Co 1957 Pp 343 40s

IN some medical schools, teaching about mental and emotional illness is still limited to a few lectures and to demonstrations of spectacular cases (Huntington's chorea, for example). Dr Balint rightly says that students are told to treat the whole patient, but are given little or no indication how to do so, which is unfortunate because much of general practice is concerned with emotional illness. The untrained doctor may do harm as Dr Bomford observed at the meeting we report on p 944, the doctor-patient relationship may sometimes be pathogenic and very occasionally lethal. Reassurance is often useless, and avuncular common-sense advice "is as limited and crude a tool as are carving-knife and screwdriver in surgery". On the other hand, there are good reasons for the deficiency most students are probably too immature to grapple with their patients' emotional difficulties, and there is little real knowledge about the treatment of whole patients that students can be taught.

Dr Balint has organised seminars at which a group of family doctors and a psychiatrist discuss patients, their objects are less to help particular patients than to train themselves in psychotherapy and to research into the illnesses encountered and the treatments needed. The group training can also help the doctor to achieve the personality change he usually needs, according to Dr Balint, to be a successful psychotherapist, for his personality determines his response to his patient and the treatment he gives. The family doctor is well placed for such work. Unlike the specialist, he sees the whole patient, whom he meets in many ways—as physician, obstetrician, psychotherapist, and family friend. He sees the patient early in the illness when the prospects for preventive work are best, and unlike the specialist he is always available. Most who have tried it find it a heavy responsibility but richly rewarding.

Dr Balint's book is based on material gathered at these seminars. It is really several books in one—an inquiry into the effect of the doctor on the patient (what he calls the pharmacology of the doctor as a drug), a plea for training in psychotherapy for suitable family doctors, a valuable source-book for anyone seeking to organise similar seminars, and a call for research into the pathology and treatment of the whole patient—which can be done only by general practitioners, and perhaps best through the type of meetings that Dr Balint describes.

Everyone will take issue with some of his ideas, but there is so crying a need for research and training on the lines he advocates, and his book is so eloquent and modest a plea, that we hope it will be read by very many family doctors, psychiatrists, and teachers of medicine.

Surgical Management of Pulmonary Tuberculosis

Editor JOHN D STEELE, M D, associate clinical professor of surgery, University of California School of Medicine. Springfield, Ill Charles C Thomas. Oxford Blackwell Scientific *Publications 1957 Pp 213 72s*

THIS monograph is dedicated to the memory of John Alexander "with the affection, admiration and gratitude" of the thoracic surgeons he trained. Similar monographs on other aspects of thoracic surgery will follow. The surgery of pulmonary tuberculosis was Alexander's first interest—and the book on which he was working at the time of his death was to have had a similar title. To produce a book which is a worthy memorial to a great figure is, however, far from easy and imposes certain limitations on editor and contributors which make repetition and stodginess hard to avoid. In the circumstances original thought is scarcely to be expected and the authors have largely resorted to a historical review supplemented by a description of technique and an assessment of results. The chief merit of the work, therefore, is as a historical document and in this respect its painstaking assiduity gives it a high standard. It is beautifully produced and the illustrations and documentation are impeccable.

In the future the book will no doubt be regarded as a monument to the era when thoracic surgery in tuberculosis was feeling its way towards the simple and effective solution ultimately provided by chemotherapy and resection. The conviction grows in the reader's mind that such procedures as cavernostomy, plombage, even thoracoplasty, are almost bygones, mainly because of chemotherapy, and it is to the credit of the editor that he has included a comprehensive review of chemotherapy, so marking the settled position it has achieved in tuberculosis treatment.

Alexander, one of the first to specialise exclusively in thoracic surgery, had a great influence on its development in the United States, and it is fitting that his merit should receive this unique tribute.

Current Therapy (Philadelphia and London W B Saunders 1958 Pp 781 84s)—Prof Howard Conn's annual is a little bigger and dearer this year, but it is a good investment for any hospital. Its principal user will probably be the houseman who wants to know quickly the modern treatment for some emergency or some condition that is uncommon or out of his experience. It would doubtless be impossible to compile a book of this sort to please everyone, but there is little here to quarrel with. Some eyebrows will rise at the injunction to prescribe dihydrostreptomycin 4 g daily for 6–8 weeks in endocarditis, and at the choice of propylthiouracil in thyrotoxicosis.

An International Symposium on *Aldosterone* (London J & A Churchill 1958 Pp 225 40s)—It is four years since aldosterone, the only adrenal hormone which seems free from pituitary control and plays a direct part in homœostasis, was isolated in crystalline form. Last June the Clinique Therapeutique of the University of Geneva organised a symposium, under the chairmanship of Prof R S Mach, and attended by European and North American workers, the proceedings are here edited by Dr Alex F Muller and Miss Cecilia M O'Connor.

have no useful advice to offer the considerable number of people who do not take their troubles to a doctor but whose way of living, if uncorrected, is sure to lead to one of the breakdowns of middle life? To such questions the answer is that sometimes, undoubtedly, the periodic examination can have good results, but that its advantages are very easily exaggerated. Contrary to what is often supposed, the approach of few disorders can be detected before symptoms appear: pneumonia, poliomyelitis, appendicitis, vascular thrombosis, and many other common illnesses strike down people in apparently perfect health. Secondly, early diagnosis does not, unfortunately, by any means certainly lead to successful cure. And thirdly, in many chronic disorders early diagnosis is not particularly important, because they can be cured equally well in the later, symptomatic stage.

The periodic overhaul has a strong appeal to a generation which thinks in terms of machines. But the human body is not a machine, and British doctors may be wise in rejecting this analogy and trying to weigh the advantages against the disadvantages—in practice not in theory. One practical disadvantage is that the cost of adding periodic examination to the amenities of the National Health Service would be enormous. In Soviet Russia a great many doctors now spend a great deal of time on examination of the healthy, and Sir JOHN CONYBEARE's [29] estimate of an extra £100 million a year for such examination is certainly not too high, if it is to be done properly. Could not this money, and the resources it implies, be used by the N.H.S. more effectively in other ways? Another and more fundamental disadvantage is that the system must, for many people, mean more thoughts about illness and more anxiety. Usually the examination itself, when the time came, would relieve such anxiety, and no doubt the majority would take their overhaul unemotionally as a matter of course. But routine checks have their psychological dangers even for the least neurotic. When a minor abnormality is found, and further tests and investigations are necessary to establish its cause, some concern is bound to be felt, and this may leave its mark even when the abnormality is finally found to be of no consequence.

If, then, periodic examination of everybody is very far from being the ideal preventive measure that it may appear, is there anything to be said for a routine health check on particular groups, as proposed by the B.B.C.? Not, we think, very much when it is only an occasional examination by a doctor who knows little or nothing of the examinee. But it may have some value in the special circumstance where a large firm or organisation employs a full-time doctor who will examine key employees at fairly short intervals, and who may be expected to know a good deal about their health and personality. As Dr R. F. GILLMER pointed out,[30] such knowledge will sometimes enable the doctor to detect early signs of physical or mental overstrain, and his detailed records may show significant changes over a period. (A good general practitioner in a reasonably small single-handed practice is in a similar position, and a system of regular examinations may help him in the management of his patients.) The B.B.C.'s scheme may therefore have some usefulness if the Corporation propose to retain one particular doctor's services, and if he is to see each senior employee at least once a year. It would cost them less if they dropped the routine electrocardiography and X-ray examination. The latter is already offered by the mass-radiography service, and in any case the worth of the examination depends on the doctor's alertness. There is a story told of a well-known contemporary American physician who was asked to see an important but ageing business man whose firm proposed to send him on a vital mission abroad. The firm had had an exhaustive series of medical tests carried out, all of which the man passed successfully. Nevertheless, the physician's advice, given after a short physical examination, was uncompromising: "Don't send him." The firm, somewhat taken aback, protested that all the tests had been satisfactory, and asked what had been missed. Back came the reply: "Egg on his waistcoat."

Annotations

HOSPITAL MEDICAL STAFFS

LAST week the Minister of Health announced agreement with the Joint Consultants Committee to set up a joint working party "to study, in the light of experience of the hospital service since 1948 and of all other relevant considerations, the principles on which the medical staffing structure in the hospital service should be organised."[1]

This is welcome news. The working party's task will presumably include a review, in some form, of consultant needs—a review which the profession's representatives have repeatedly called for, and in which attention will no doubt be given to the unequal distribution of consultants[2] and to consultant work now done by others. But the working party will be concerned with larger issues. In particular it will want to discover whether, under the existing system, peripheral hospitals can continue to secure enough medical staff below consultant level. The number of registrars is fixed by other factors than the convenience of the hospital, and there is no inherent reason why this number should suffice for all demands; indeed there are increasing indications that it does not suffice. For instance, last month Luton and Hitchin Hospital Management Committee, impressed by the difficulty of filling the two registrarships in anæsthesia at Luton and Dunstable Hospital, decided to seek permission to regrade one post as that of S.H.M.O. The committee was informed that there are some registrars who, though unlikely to obtain the highest qualifications and become consultants, are nevertheless competent anæsthetists and valuable members of hospital staffs.[3]

We ourselves know of no sound evidence that the existing medical-staff structure, with the long leap from senior registrarship to a consultant post, has favoured efficiency in the hospital service, and it has even operated

agrees with MORTENSEN[19] that this complication is far less common today[20] Bleeding, on the other hand, is certainly heavier when the prostate is approached by the retropubic than by the transvesical route[21 22], and "inspection of the sucker bottle and the swabs at the end of each operation will justify the routine administration of 600 cc of blood in all cases"[11]

If minor differences in operative technique are unlikely to arouse much controversy, the same may not be true of postoperative management In addition to ADAMS's[23] "third ureter"—a ureteric catheter introduced either suprapubically or alongside the urethral catheter—MCEACHERN administers for the first twelve to twenty-four hours after operation an intravenous drip, somewhat fancifully referred to as the "fourth ureter"

Few will dispute that the parenteral administration of fluids has many advantages over "pressing fluids" by mouth, but that "the third ureter compensates for, while the fourth ureter overcomes, Nature's postoperative oliguria"[11] is only true if these terms are interpreted so widely as to lose all meaning "Nature's postoperative oliguria" is part of the body's complex response to any form of trauma, and far from being amenable to correction by intravenous fluids, it is likely to be aggravated by it The "third ureter" does correct postoperative oliguria in the sense that it contributes a flushing system while there is danger of bleeding and of catheter blockage But the "fourth ureter" does nothing to overcome it What it does do is to correct the very reverse—namely, the excessive loss of water and electrolytes which may follow relief of long-standing obstruction

Patients with chronic urinary obstruction tend to accumulate a backlog of salt and crystalloids, shown in part by œdema, a high blood-urea-nitrogen, and a total plasma osmolarity higher than the sum of measurable anions and cations Some desalting and hæmoconcentration may result from vomiting and from pulmonary water loss, but the "dehydrated" appearance of these patients is usually due to uræmia, and they are, in fact, grossly waterlogged As soon as obstruction is relieved—whether by simple catheterisation or by prostatectomy—solute diuresis begins If renal function is normal this is a transient phase, the renal tubular cells quickly regain their ability to process the filtrate and to concentrate the urine, and dehydration and desalting remain minimal In older patients, however, some tubular damage is common, and the postobstructive diuresis may result in severe salt and water depletion, hæmoconcentration, and decrease in plasma-volume[24] In addition, there is a tendency to acidosis, suggesting impairment of the enzyme systems in the proximal tubules[24] 5–8 litres of urine of fixed specific gravity may be passed in twenty-four hours, and the sodium loss may be massive (Largely according to the water balance, this may lead to a significant fall in the plasma as well as the total sodium concentration)

The guiding principle of intravenous-fluid therapy after prostatectomy should be to preserve the precarious postobstructive fluid balance rather than to maintain a steady stream down the ureters MOORE[24] believes that "this is one of the few situations in surgery where a conscientious attempt should be made each day to repair the urinary loss of sodium salts", and large infusions of sodium bicarbonate or lactate may be required This is no easy task, especially postoperatively, and clinical judgment must temper biochemical considerations (In the presence of pitting œdema, or of other evidence of increased total body sodium, it may be wise, for instance, to allow the sodium drain to proceed for a few days before any attempt is made to repair the loss)

Most surgeons will agree with MCEACHERN that the indwelling catheter is "the pivot on which the whole technique of modern postoperative management depends", and that "there is no aspect of surgery in which trained and experienced nursing is more necessary"[11 20] There is, on the other hand, much to be said for not laying down a definite time after which the catheter should be removed The correct time is neither two days nor two weeks after the operation, but whenever the patient can empty his bladder unaided and completely A late postoperative complication which has caused some concern at the Royal Adelaide Hospital is postmeatal stricture Its frequency seems to be increasing, but its causes remain obscure MCEACHERN suggests that several factors may have to be considered: the size of the catheter in relation to the calibre of the urethra, the duration of catheter drainage, chemical irritation by certain types of red rubber,[25] and altered tissue response to infection as a result of chemotherapy[26] Fortunately this complication is of importance only when neglected, and in only 2 patients of the Adelaide series was repeated dilatation necessary

Routine Medical Examinations

THE practice of visiting a doctor or clinic regularly for a routine "health check" has long been common among the wealthier citizens of the United States, and there are signs of its increase in this country The value of such examinations, which may include radiography, electrocardiography, and laboratory tests, has lately been the subject of correspondence in *The Times* When Captain L P S ORR, M P,[27] asked whether it is proper for the British Broadcasting Corporation to spend public funds on private routine examinations for its senior executives, the B B C chairman[28] replied that £900 a year is "a small premium to pay towards the maintenance of the health of trained senior staff" Whereupon several distinguished physicians declared that routine examinations of this kind are virtually useless for their intended purpose—namely, the detection and successful treatment of symptomless disease

Some readers of *The Times* will have discounted these medical utterances on the ground that doctors in general are commonly more interested in treatment than prevention Such critics can point not only to America but also to Soviet Russia, where periodic examinations are officially regarded as a most desirable development in medicine, because they bring disease to notice at an earlier and more readily treatable stage Is it not a fact (they may say) that many patients suppress and conceal serious symptoms which a routine examination would soon elicit? Would the profession avascular necrosis is inevitable) In these cases it is important not to discard clinical judgement, and the surgeon who examines his own radiograph is more likely to spot the minor lesions Among the most difficult of these to discover is the small stress fracture, and Burrows[8] has emphasised that many views of the tibia may be necessary to demonstrate the small area of stress infraction In many cases we undoubtedly lay too much stress on the slight lesion of the bone and forget or ignore the extensive soft-tissue destruction with which this may be associated

INFANTILE SCURVY IN CANADA

THE incidence of scurvy in infants has shown a decided rise in Toronto in recent years, and Whelen et al[9] have described the clinical findings, feeding histories, and errors in diagnosis in 79 cases treated in the wards of the Hospital for Sick Children, Toronto, in the five-year period 1951–55 Until 1953 the average yearly total of admissions for scurvy over a period of twenty-six years had only been 7, whereas in 1954 it was 46 Half of these patients lived in Toronto The age at onset of symptoms and the clinical manifestations were typical and call for no special comment What is surprising is that in this age of vitamin-consciousness the disease should show a striking rise in incidence (which is apparently also evident in Winnipeg) in a city with a good record for pædiatric services and public health

The cause was clear Nearly four-fifths of the infants had not received either suitable fruit juices or synthetic ascorbic acid for six weeks before admission In two-fifths some orange juice had been offered in the early months but had not been persisted with The average duration of breast-feeding in the series was less than 11 days, and the alternatives as regards milk—evaporated or pasteurised liquid milk—did not contain enough vitamin C The infants in the hospital invariably improved rapidly when given therapeutic doses of vitamin C, and this was held to discount the statement of parents in a fifth of the series that their children had been given enough of the vitamin in their diet The next question was whether in these instances, or in any of the series, " the well-meaning but unnecessary manipulations of the most imaginative mother " had destroyed the vitamin C in any of the fruit juices used Surprisingly, in view of the general impression that heat will destroy vitamin C, the Toronto workers found that the addition of boiling water, boiling the orange juice, alkalinisation, and alkalinisation followed by boiling, applied to fresh, tinned, or reconstituted frozen concentrated orange juice, did not reduce the vitamin-C content to a dangerously low level Even boiling for forty minutes " in an uncovered, chipped, rusty, enamelled saucepan " reduced by only 15–25 5% the vitamin C measured by decolorisation of the accepted phenolindophenol dye solution

These results are important in view of the alarm expressed by Moncrieff[10] at the use of the pasteurised orange juice now supplied by certain milk firms for babies and young children The plain fact seems to be that babies get scurvy because they do not receive orange juice at all One reason is thought to be the unnecessary use of synthetic multiple-vitamin preparations which may not, in fact, contain any vitamin C One of the suggestions made by Whelen et al is that vitamin C might be incorporated into certain foodstuffs commonly consumed by infants, as is done with vitamin D in evaporated milk Every infant requires at least 30 mg of vitamin C daily, and this, it is suggested, should be emphasised more strongly by doctors and others concerned with the supervision of infant feeding

OVERSEAS STUDENTS AND POSTGRADUATE STUDY

ORGANISERS of postgraduate medical education in this country have no easy task their sails have to be trimmed to many winds The clinical requirements in Great Britain are a world away from those in remote tropical or deprived communities, and these, again, differ from the demands of our wealthy and energetic Dominions In the great days of British rule overseas, students automatically turned to Britain for training in our views and methods Of late years some things have changed, but tradition and prestige, and perhaps proved value, still ensure a flow of men and women from all parts it is often said, too, in poorer countries that there is more of relevance to be learnt from our financially restricted health-service system than from affluent and uncontrolled American methods It is an honour to us that they come, though we should not assume it is purely a love of Britain and of knowledge that brings them the coveted diploma often means everything Obviously we as a nation benefit from these contacts on many fronts other than the purely scientific, and we should ask ourselves from time to time whether we are giving these friends from abroad what they need, and whether we are giving it to them well enough

Dr Cicely Williams, writing in this issue and the last on child welfare, clearly thinks that we are not Her penetrating remarks are derived from observations in South East Asia and Africa She says with reason that a study of rare disorders in the Western setting of large institutions is not much help (and may even be a hindrance) to the doctor from a far-off land Though Dr Williams may take an over-rosy view of the potential sociological importance of doctors, it could be said that others besides our overseas colleagues would benefit from greater understanding of social factors (for example, in smoking and dietary fat) If we feel that our foreign contacts are worth encouraging (and surely they are) perhaps we should readjust our emphasis Clearly it is out of proportion for an Asian to be examined in detail on the Klippel-Feil syndrome and not on kala azar, similarly it is unnecessary for the provincial specialist here to be acquainted with recent trends in leprology There seems to be room for some curricular adjustment, and there might be advantages in an alternative second paper in some of our specialist diplomas, dealing with tropical, nutritional, social, and public-health questions It would tax the resources of our teachers, for, while many have had tropical experience in the Armed Services, this does not help much in the understanding of village life and problems Short visits to these countries do not help much either, since, as Dr Williams points out, it is not easy for the European specialist to see beyond the shiny new prestige institutions to the neglected aspects of medical and social life Even a doctor in daily contact with Indian rural patients may be amazed at his ignorance of their everyday beliefs and superstitions, lately described by Carstairs[1] against some of the staff themselves—notably those senior registrars who have failed to make the leap, and senior hospital medical officers who have been largely excluded from the competition In the short run, insistence that (with stated exceptions) permanent medical staff shall be grouped together as consultants has favoured those of them who, relatively, apply less skill or carry less responsibility than some of their colleagues In the long run this grouping may tend to operate against those with relatively higher skill or a heavier responsibility We have more than once expressed the belief that both the hospital service and the profession would have cause to welcome the abolition of the SHMO grade and the creation of a new one—that of specialist—to include all on the road to a consultant post besides some who aspire to go no further[4] Not all our readers subscribe to this view[5] But both those who do and those who do not will look with relief to the working party as a medium for discovering facts that may open a way out of the present damaging impasse

[1] Carstairs, G M The Twice-Born London, 1957

The help meanwhile proposed by the Minister for some time-expired registrars[1] takes a devious and obscure form, but the Minister's hands are partly tied by the Royal Commission on Remuneration and by the Government's avowed determination to avert a general increase in salaries and wages We see no reason to doubt the sincerity of his assurance that the new posts for selected senior registrars, with security of tenure and a somewhat higher salary, are to be provided " pending and without prejudice to the working party's report " and " are not to be regarded as a substitute for additional consultant posts " Certainly, we should not wish to see the present first-aid measure cited as a precedent for setting up an intermediate grade If (as we hope) such a grade is to come it should be introduced deliberately, frankly, and if possible by general consent

MODIFIED ASPIRIN

ASPIRIN, the wonder drug of the time when it was introduced, is still unsurpassed in its field Idiosyncrasy to it is very rare, but occasionally it causes gastrointestinal hæmorrhage, probably owing to gastric erosions, and less rarely it gives rise to symptoms of gastric irritation The forms, and the prices, of aspirin preparations vary widely Aspirin *B P* gr 5 costs a hospital 9*d* per 100, whereas a proprietary preparation containing aspirin gr 5 with aluminium glycinate and magnesium carbonate costs 6*s* 6*d* plus 1*s* 11½*d* purchase-tax A high price is sometimes put on preparations claimed to be exceptionally pure, but today it is unlikely that impure aspirin is sold, the production of salicylic acid by hydrolysis is prevented by airtight storage

The effectiveness of mixtures of aspirin with other analgesics, such as codeine, depends mainly on their aspirin content, the small amount of codeine, though of little therapeutic value, produces constipation in some patients Calcium or soluble aspirin is about equal in analgesic effect to aspirin, but is often preferred because of its lesser tendency to produce gastric effects Crushing aspirin is perhaps equally efficacious, though less convenient, but a badly made aspirin tablet may disintegrate slowly, and in this respect calcium aspirin is better

Sodium bicarbonate was once prescribed with sodium salicylate to minimise gastric irritation Behind this may have lurked the idea of " acidosis " brought about by salicylism—though, as we now know, salicylate causes overbreathing with subsequent alkalosis Mixing aspirin with a buffer seemed a logical development to the incorporation of bicarbonate with salicylate, and several reports suggested that gastric distress was less common with buffered aspirin than with ordinary aspirin[1–4] But studies conducted by blind random selection techniques have failed to show any difference between the two forms[5, 6], and blood-salicylate curves were found to be the same (Batterman[5] showed that the incorporation of bicarbonate 1 2 g with aspirin 0 6 g lowered the free and total plasma-salicylate levels, thus confirming an earlier assumption) Further tests on buffered and simple aspirin are needed in order to establish beyond doubt their value in relation to each other

OCCULT FRACTURES

DIAGNOSIS of the fracture that is suspected clinically but cannot be demonstrated radiographically is an important orthopædic problem It arises most commonly in the wrist, a fracture of the carpal scaphoid may not be apparent on the radiograph until several weeks after it has been sustained Waiting for radiographic evidence in these patients may invite delay in union and ischæmic changes in the proximal fragment of the bone, yet it is scarcely more satisfactory to immobilise in plaster all patients with the clinical signs of a scaphoid fracture, since many will resolve without a fracture ever becoming visible

In children spiral fractures of long bones commonly do not show on the early radiographs, and very often confirmation of a clinical diagnosis depends on the later X rays Sometimes the only change which ever becomes apparent is periosteal thickening, but more commonly the fracture is seen some two or three weeks after the injury Fractures near the epiphyses of long bones may also be difficult to display, but in this region immobilisation is less important In the upper limb of the adult minor fractures of the neck of the radius or chip fractures of the head of the radius may become apparent only after repeated radiographs have been taken, and special views in many positions may be necessary In the hip the undisplaced fracture of the neck of the femur is still occasionally misdiagnosed Many of these patients will recover full function without any relief from weight-bearing, but in others the diagnostic failure results in non-union or avascular necrosis of the head of the femur Fractures of the spine may be missed because the radiographs show little or no deformity, but this error in diagnosis is often of little importance since slight injuries to the vertebral body can well be treated by early exercises and mobilisation

Reich and Rosenberg[7] emphasise the importance of relating the clinical to the radiological signs They define the occult fracture as one which gives clinical signs of its presence but cannot be demonstrated by X-ray examination until reparative changes have occurred (Perhaps this is an over-optimistic definition since some of the fractures may not be diagnosed until delay in union or

FAST AND SLOW STREAM MEDICAL WARDS

JOHN NAISH
M.A., M.D.Cantab., F.R.C.P.
CONSULTANT PHYSICIAN, BRISTOL CLINICAL AREA

JUST as road travel is improved by the provision of fast and slow lanes, so the diagnosis and treatment of medical patients could be made more efficient by the care of patients in wards with a fast or a slow rate of turnover of beds.

In the past this division has taken place, but between hospitals rather than between wards. The slow-stream wards are concentrated in special hospitals for the chronic and elderly sick. Anyone who has worked in such a hospital knows, however, that many of the patients admitted are in need of just the same diagnostic skills and treatment as the patients who happen to be admitted to a general hospital. Often it is the availability of beds at the time of a request for emergency admission that determines whether a patient of 60–65 is admitted to a geriatric hospital or to the wards of a general hospital; this is tantamount to saying that the decision is largely one of chance. If the patient admitted to a geriatric unit is found to require investigation or treatment which cannot be provided at that hospital, he must be transferred to a general hospital. If, on the other hand, it is found that the patient admitted to a general hospital is unlikely to get well within three to six months, it may be desirable to transfer him to a geriatric hospital. Such transfers are difficult to achieve unless the physician-in-charge has beds at both hospitals, and in any case they are administratively wasteful and emotionally damaging to the patient.

One may hear physicians and surgeons who work in a hospital where the weekly cost of an occupied bed is £25 or more complain because they cannot easily transfer their more chronic patients to a geriatric hospital, and on the same day listen to the grumbles of geriatricians who find themselves dealing with certain inpatients for whom they have inadequate facilities for investigation and treatment. I repudiate the suggestion that all elderly sick patients need full investigatory facilities. The clinical senses are usually quite sufficient to reach an accurate diagnosis and prognosis, but there are some cases where careful investigation is necessary and useful.

The problem is more one of the slow recovery and of social difficulties to be overcome before the patient is discharged. This sort of patient can be inexpensive to nurse and to treat, but he needs a hospital bed for longer than a young patient admitted for—shall we say—stabilisation of his diabetes. The overall cost of his treatment may be much the same as that of the younger patient who in his shorter stay uses up more of the time of highly trained, highly paid staff, and makes fuller use of expensive diagnostic facilities.

Therefore we have on the one hand a need for acute wards, fully staffed by highly skilled personnel, in which the turnover is so rapid that 30 patients per annum can be treated per bed. On the other hand there is need for slow-stream wards staffed by the same medical team, but with a different grade of nurses, where the need for investigation is less, and the emphasis on nutrition, rehabilitation, and nursing care is greater.

Acute wards usually contain 25% of ambulant patients admitted for special investigations, 25% acutely ill and requiring hour-to-hour treatment or intravenous therapy, and the remainder recovering from acute illness or being treated in bed. The slow-stream wards usually contain 20% bedfast patients with dementia or various forms of paralysis, 20% of patients who are likely to die within six months from carcinoma or other fatal diseases, 20% frail ambulant patients who are unable for social reasons to maintain a reasonable life outside a hospital, and the remaining 40% elderly but capable of recovery, given time and patient effort—cases of congestive heart-failure, hemiplegia, and chronic lung disease. In such wards it should be possible to treat 4 patients per bed per year.

The present trend towards the development of geriatric and exclusively acute general hospitals leads to an inequitable distribution of nursing staff. The geriatric hospitals have the greatest difficulty in recruiting staff in spite of State enrolled assistant nurses scheme, and the free use of nursing auxiliaries. The teaching hospitals have nurses to spare (though this would rarely be admitted), and these nurses sometimes have little experience of the nursing of the elderly sick. This is a pity because in the next twenty years we must face a 14% increase in the numbers of elderly sick. It is fortunate that many elderly patients are in fact nursed and treated in acute general hospitals today, but it is nevertheless a pity that nurses in training see little of the intensive methods of rehabilitation and perhaps do not experience the different mental approach needed in the care of the elderly sick.

THE OBSTACLES

One of the main obstacles to the integration of acute and geriatric medicine in hospitals is the policy of the General Nursing Council, which makes it difficult to house training schools for State-registered nurses, and State enrolled assistant nurses in the same hospital. Nurses under S.E.A.N. training may not work in the same wards as nurses under S.R.N. training. At the time ten years ago when it was clear that many hospitals would have to close down unless a shorter course of nurse-training could be provided, the State enrolled assistant nurses scheme was born of necessity. After this lapse of time, it must be clear that the standards of nursing have not suffered by the introduction of the State enrolled assistant nurses scheme, and State-registered nurses have not contracted any dread diseases from working in close proximity to State enrolled assistant nurses.

Another obstacle to the inclusion of slow-stream wards in acute hospitals is the system of classification of hospital by the Ministry of Health into, "acute", "mainly acute", &c.—each with its own scale of finance. This makes the hospital management committees, which are jealous of the status of their hospital and anxious for the fullest financial provision, unwilling to admit more than a very small proportion of elderly sick patients, and certainly unwilling to segregate them in special wards.

A third difficulty is the attitude of the medical profession. Those working exclusively in acute hospitals may see themselves as a superior breed who should not be troubled by the problems of those patients who obstinately refuse to get better within a month, or they may be interested mainly in their specialty. Whatever the reason, there is resistance to the incorporation of geriatric services into an acute hospital, which seems hardly justified when the complaint is so often heard that such and such a "chronic hospital" will not take

If, however, the training and diplomas we have to offer are not (through other eyes) all they might be, it is also sadly true that foreign students arriving here are sometimes inadequately prepared for them Linguistic and academic difficulties added to those of everyday adaptation may plunge a young doctor out of his depth, and he may never really resurface Something more could be done from both ends by way of selection and preparation, although some Governments and the British Council already do valuable work We believe that if Britain (and especially London) is to remain a sought-after centre of teaching and research it must broaden its horizons Dr Williams has told us something of what is needed from the pædiatricians her words are wise and deserve careful study

NARROWED ATTENTION

STRONG emotion, acute stress, or the action of certain drugs can dramatically reduce awareness of the immediate environment Callaway and Dembo [1] discuss the possible neurophysiological basis for this familiar phenomenon, for which they suggest the term "narrowed attention", and which, in their view, is something other than altered ability to sense or respond to a stimulus It is, they believe, rather a change in the process which determines to what extent behaviour shall be influenced, at a given time, by each possible source of stimuli The more a person's attention is "narrowed", the less will his behaviour be influenced by factors peripheral (in time or space) to the focus of attention

Callaway and Dembo believe that "narrowed attention" augments internal sources of motivation, that it is associated with (but is not the result of) central sympathomimetic activity, and that both phenomena are perhaps secondary to stimulation of the brain-stem reticular formation To establish the correlation between "narrowed attention" and central sympathomimetic activity, they observed the effect on their subjects' behaviour of sympathomimetic drugs They report that amyl nitrite, adrenaline, and methamphetamine produced changes in size-matching, nerve-gases, amyl nitrite, and methamphetamine produced changes in muscle response to loud sounds, and methamphetamine produced changes in galvanic skin response and in guessing behaviour All the changes were indicative of "narrowed attention"

Calloway and Dembo remind us of the everyday instances of narrowed attention people may become "blind with rage", or the football player ignore his injured hand in the heat of the game, and they quote Kinsey's [2] finding that orgasm narrows attention, and Shipman's [3] that children, waiting at the dentist's, recall fewer details of their surroundings than do controls Callaway and Dembo mention two instances in which, during their experiments, subjects showed "narrowed attention" apart from their experimental responses One student with a broken arm in a cast felt less uncomfortably aware of it under methamphetamine The same drug led another student to be blind to the polite rebuffs he encountered while trying to "date" a female technician, and to desist only when faced with a flat refusal From the clinical viewpoint, they suggest that the action of methamphetamine in improving the behaviour of hyperkinetic children, described by Laufer et al [4] as "unusually sensitive to stimuli flooding in from both peripheral receptors and viscera", may be related to the narrowing of attention produced by the drug

This study will encourage other approaches to the problem of the relation between sensory stimuli and internal processes

MENTAL ILLNESS AND SOCIAL CLASS

THERE has been an increasing trend in medicine lately for the searchlight to be turned, as it were, inwards towards us, the doctors On an organic level we all know of the survey into our smoking habits, and we should be glad indeed to find out why we seem so liable to coronary-artery disease The psychoanalysts take the investigation of the doctor further than others, insisting that the aspiring therapist undergo a long and difficult training analysis that will give him insight into his own mental mechanisms Merton [1] recently summarised some of the sociological work done in medical schools in the United States, and there have been studies of mental hospitals and their personnel [2 3] The permeation of anthropological and sociological influence is particularly seen in investigations of mental illness, though the fusion of specialties is by no means always friction-free [4] The United States is clearly far ahead of us in this type of project

On April 17 Prof A B Hollingshead, the distinguished sociologist from Yale University, outlined at the Maudsley Hospital some of his work with Dr F C Redlich,[5] on mental illness and social class, especially that related to the practice of different psychiatrists and psychiatric institutions He studied all those resident in New Haven (Connecticut) who, during six months in 1950, had undergone psychiatric treatment, wherever that treatment had been given He graded the 1900-odd cases according to his 5-scale social-class system [6] and correlated this with the type, place, and duration of therapy Some expectations were confirmed—for example, that psychoanalysis was almost exclusive to the richer classes, whereas the poorer made do with simple and brief measures For the psychoses he showed that the wealthier patients received earlier treatment and were discharged from hospital more quickly, but that they were readmitted more frequently A more surprising finding was that therapy correlated little with diagnosis, and that the type of treatment was therefore more or less determined before the patient ever met the doctor he had selected Professor Hollingshead noted the division between those psychiatrists who used physical treatments and those who eschewed them and concentrated exclusively on psychological methods and interpretations The two schools are certainly to be found in this country,[7] but here, apparently, the boundaries are less clear-cut

It seems, therefore, that just as a person's class position determines his place of residence, friends and hobbies, so it decides—anyhow in the United States—the therapy he will receive when mentally ill Perhaps Professor Hollingshead will one day tell us to what extent it determines the type of illness he will get A similar piece of research in this country would not be easy, but might be rewarding, and a survey of the views and methods of all psychiatrists within six miles of St Pancras would be worth attempting

centuries, but now, by newspaper articles and advertisements, it has been made into a respectable symptom

If there is any real increase in tension it may well be the result of tranquillisers, because their withdrawal encourages the symptom to develop

Irritability is another symptom often treated by sedation. Caution is particularly necessary here because irritability may so easily be a manifestation of physical illness—thyrotoxicosis or peptic ulcer—and sedation may mask the underlying disease

PHARMACOLOGICAL SEDATION

Two groups of drugs are used in sedation—hypnotics and tranquillisers

Hypnotics are liable to produce a befuddled kind of sedation, and have the further disadvantage that psychoneurotics may save them up for half-hearted suicidal attempts Moreover, people weak in character may become addicts

Tranquillisers belong to four main groups

The rauwolfia group
The chlorpromazine group
The benzhydrol group—azacyclonol, benactyzine, and others
The muscular relaxants related to mephenesin, of which meprobamate is the most widely known, the most widely swallowed, and perhaps the most expensive of all the tranquillisers

Each group has good points and disadvantages The rauwolfia group may calm grossly disturbed psychotics but sometimes produces severe depression. The chlorpromazine group achieves dramatic results in some psychotics with gross excitement or tension, but has many side-effects including obstructive jaundice The benzhydrol group are specific in combating the madness produced by the administration of lysergic acid or mescaline, but the treatment here should be to withhold these drugs rather than to neutralise their effects Otherwise the benzhydrol group, on controlled testing, have shown little outstanding value The last group, the muscular relaxant meprobramate compounds, have become the rage in America. Their tendency to produce addiction to larger and larger doses and their high cost (over twenty times that of amylobarbitone) mean that much caution must be used in prescribing them

Every sedative drug has imperfections, and the search for the perfect one will continue—" since ", as Aldous Huxley remarks, " reality, however Utopian, is something from which people feel the need of taking pretty frequent holidays "

OTHER MEANS OF SEDATION

But sedation is not by pharmacy alone There are the social sedatives, tobacco and alcohol, which give rise to much pleasure but also much illness There are physical means of sedation—massage, warmth, and appropriate sights and sounds, particularly those of a monotonous or repetitive kind (I have observed that housewives appear to achieve a kind of group sedative ecstasy when seated in rows watching their laundry gyrating interminably behind the portholes of a washing-machine) For many people activity is the best sedative, and Kipling prescribed it for that common psychoneurosis—the hump The sedative effect of music is well known to mothers singing their babies to sleep with a lullaby, and an interesting example of the use of sound in sedation is that of Sir Despard Murgatroyd in *Ruddigore*, who tranquillised his wife, whenever she was getting out of hand, by merely saying " Basingstoke, Basingstoke, my dear ’

Nevertheless, though sedation can be achieved with the use of drugs, heat, sight, or sound, it is more logical to quieten a mind directly than by stupefying its physical casing Despair is best treated with hope, not dope Psychotherapy is the basis of all sedation and the use of drugs must be subservient to it—a temporary measure to tide a patient through a critical phase, not a permanent requirement like insulin for diabetes The technique of such psychotherapy is not easily taught. The secret of it is the art of listening—allowing disturbed patients to unburden their load of tribulations Even though most of the burden has to be shouldered again after the interview, it is easier to bear if somebody else has seen how heavy it is A problem is easier to countenance if it has been aired and put into words I felt rather small recently when a father, thanking me for giving some psychological treatment to his son, said " I think it's done him a lot of good being able to tell all his troubles to someone. When I was his age, I used to tell all my troubles to a large rubber duck, and it seemed a great help I suppose you're much the same sort of thing " I had not previously considered myself as the therapeutic equivalent of a large rubber duck, and found it both humbling and enlightening

Yet sedative psychotherapy is not achieved solely by listening The doctor, however effective a rubber duck he may be, has to emit an occasional quack Talking to patients or to their relations is an art that cannot be taught. Only experience and instinct will give a doctor the knowledge of when to probe and when to leave alone when to chide and when to reassure, when to speak and when to remain silent.

STIMULATION AND SEDATION

Most of what I have said about sedation applies again to stimulation. Stimulation can be achieved by drugs (ephedrines, amphetamines, and others), by social stimulants (tea and coffee), by physical means (cold baths), and finally by psychological means (stimulating music, stimulating conversation, and, very rarely, stimulating lectures or speeches)

One man's stimulus is another man's sedative, and the strictures that I mentioned earlier about sedatives apply to pharmacological stimulants They too should be used only to tide a patient through a critical phase, not a permanent requirement like insulin for a diabetic. Today we often find sedatives and stimulants are being prescribed together both too lavishly and for too long

Lately I saw a nervous young woman, who had been attending another hospital for several years She was receiving quinalbarbitone sodium gr 3 twice daily, amylobarbitone sodium gr 6 every night, and two capsules of prolonged-action amphetamine compound daily, together with one and a half hours' group therapy once weekly, and half an hour's individual psychiatric interviews twice a week. She was not any better!

Such extravagance can be expensive, dangerous and unhelpful

Stimulants are necessary to savour the humdrum and to enliven the drab, but they must be used sparingly, over-stimulated senses are less perceptive The palate repeatedly soused with vinegar is less likely to enjoy the flavour of zambaglione

The amount of stimulation available to modern man is increasing and has perhaps reached its apotheosis at Las Vegas, a city wholly dedicated to pleasure, boasting a twenty-four-hour service of every kind of entertainment and refreshment. Beside every hotel bed is a Bible and a free packet of ‘ No-Doze ’ tablets A notice reminds the visitor " If you go to sleep in Las Vegas you are not pulling your weight. You are here to enjoy yourself Help yourself to No-Doze tablets " Another the chronic cases they wish to transfer Surely the solution to this problem is to have the chronic beds under their own care and under the same roof as the acute cases This is, of course, a problem which affects physicians more than it does surgeons, but the surgeons and orthopædic surgeons should be glad to have slow-stream beds in their own hospitals to which they could transfer patients by asking a physician to " see and take over "

Then lastly there is the question of finance Could such a scheme cost more than the present plan of segregation? I think that there would be certain savings in transport, duplication of case-records, and movements of staff Expense might rise owing to the greater use of investigatory and treatment facilities for elderly patients, but this may prove an economy in the long view Provided that we face the fact that the elderly, chronic, or subacute sick need to be nursed and treated in a different type of ward, with a different type of nursing staff, and that the physicians responsible realise that they must look at their patients with the low-power rather than the high-power of their minds' " microscope ", then there is no real reason why expenses should rise Much will depend on the guiding influence of the physician-in-charge, and much will depend on a clear-headed outlook of the hospital management committee It should be accepted, for example, that slow-stream beds could be closer together than acute beds, but day-room facilities are essential, and a few physiotherapeutic tools, such as walking-machines and parallel bars, should be kept close to the slow-stream wards, and not necessarily in the main physiotherapy department

ADVANTAGES

If the integration of slow and fast stream medicine is accepted as a valuable policy for the future, there should be no difficulty in achieving the end, for the means are easily available Already, by the sheer necessities of staff recruitment, the geriatric hospitals are developing acute wards, X-ray departments, and pathological laboratories so that a more interesting type of patient can be admitted and cured It is only in this way that they can hope to recruit nursing and medical staff to care for the slow moving type of case The next necessity is for the acute general hospitals to accept in their planning a provision for slow-stream wards to be run in parallel with their fast-stream wards One medical team of two physicians should be able to staff two fast-stream wards of 30 beds each, and two slow-stream wards of 30–40 beds each, making a block of 120–140 beds

By this scheme it should be possible to make the fast-stream wards really efficient with a high rate of turnover of cases, since any patient likely to block a bed, but no longer needing special facilities such as transfusion, can be transferred to the slow-stream ward where the emphasis is more on rehabilitation and liaison with social-welfare organisations than on the intricacies of modern treatment The same physician should care for the patient throughout, so that he cannot regard the slow-stream ward as a " dump " for his less successful cases but as a place where illness is alleviated or managed as well as it can be All new patients should be admitted first to the fast-stream ward, unless the diagnosis has been fully established before admission and the case is better dealt with in a slow-stream ward

Such a policy of integration is probably acceptable to or accepted by regional hospital boards because they are well aware of the difficulties in recruiting staff to exclusively geriatric hospitals My purpose is to raise the matter at medical level—to show the positive advantages to a physician in having acute and chronic beds under his care, and the improvements in turnover and standards of medical care which could follow from such integration At nursing level, it is most important to appreciate the great differences between the care and treatment necessary for a young woman in an addisonian crisis (where the nurse must possess medical knowledge, skill, and great powers of observation) and the care and treatment of an 80-year-old lady with a hemiplegia, where all the old nursing virtues of good lifting, cleaning, and care and kindness must be brought into play and where often a devoted State enrolled assistant nurse will do better than a clever student nurse Surely it is time to drop the segregation of S R N trainees and S E A N trainees, and to recognise that both grades are necessary, useful, and capable of mixing together without harm to their professional standards

If we can look at our medical patients and after diagnosis sort them into those requiring fast-stream and those requiring slow-stream management, I believe we shall do much to improve the efficiency of the medical care of the elderly—already so large a part of our work—and we shall correct the anomalies of the present system where it is often a matter of chance whether a patient occupies a bed in one hospital costing £25 a week for his treatment, or in another costing £12 a week

I should like to thank Dr G C Kelly, of the South Western Regional Hospital Board, for his helpful criticism

Points of View

THE SEDATION AND STIMULATION OF MAN *

Richard Asher
M D Lond, F R C P
PHYSICIAN, CENTRAL MIDDLESEX HOSPITAL, LONDON, N W 10

People with stress, tension, and irritability feel the need for sedatives, and those with fatigue, apathy, or boredom seek stimulation

NEED FOR SEDATION

Stress—The increase in the pace and complexity of civilised urban life can be easily blamed for any increase in nervous illnesses To believe one is under stress or strain is easy and acceptable Acceptable to doctors because it explains much that cannot be otherwise explained, acceptable to patients because it excuses much that could not otherwise be excused, and to drug houses because it provides a demand for drugs that would not otherwise be demanded Yet we should not equate speed and complexity with stress and strain Cavemen probably suffered as much strain over the problem of choosing the right cave as business men suffer today over choosing the right stocks and shares

Tension—By this vague word, I mean a sensation of inward excitement, but not pleasant excitement—akin to anxiety or apprehension, but with no awareness of what is apprehended The patient with tension is waiting all the time for something important to happen " *I don't seem able to relax* "

I believe the increase of tension, too, is more apparent than real Under different names, it has troubled men for unresponsive until the arrival of the next R wave The Q-T interval may be estimated[8] from the expression Q-T$=0\,385\sqrt{C}$, where C is the interval between successive beats Ordinarily, the Q-T interval lies between 0 3 and 0 4 second, but some form of variable delay is desirable to deal with the range which may be found in clinical practice Visual indicators, in the shape of miniature cathode-ray tubes (the "magic eye" tuning indicators of radio sets) are a useful addition to the C T—one to show the arrival of the R wave, and the other to show the output from the integrator

ELECTRODE DESIGN

Boyd and Eadie[3] describe the types of electrodes which they found most reliable In an anæsthetised patient, ordinary needle electrodes inserted in the chest wall were the best, for a conscious patient, a chest electrode (preferably earthed) and an electrode on the left leg gave the most satisfactory results A form of electrode, which might be even better for some investigations, has been perfected in the Psychological Research Laboratory of Electrical and Musical Industries,[9] for research in electro-oculography where potential differences of the order of 20 microvolts have to be detected and measured The electrodes are of high-purity silver, kept as free as possible from all contamination Contact is made to the inner skin, after the epidermis has been removed with a dental burr, the operation is painless and penetration is too shallow to cause bleeding The electrodes are held in place by suction-cups filled with saline solution, thus eliminating the various zero frequency potentials in the electrodes themselves and on the skin

In 1956, Manzotti[10] published details of another T C circuit He eliminated muscle-potential interference by using a band-pass filter, centred on a frequency of 12 cycles a second, the design is rather critical, as such circuits tend to "ring" unless heavily damped, and damping reduces the upper limit of the counting-rate Mains interference was removed by using a balanced amplifier to provide degeneration of any signal which appeared symmetrically in each input lead

An entirely new C T circuit has been devised by the staff of the Clothing and Stores Experimental Establishment of the Ministry of Supply First shown publicly at the Instruments, Electronics, and Automation Exhibition at Olympia last May, it is a telemetering system effective over a distance of up to half a mile, intended to measure the heart-rate during violent physical exercise, such as negotiating an assault course Electrode and muscle action potentials are got rid of by sampling and amplifying the electrical activity from three different areas of the body These amplified outputs are fed to a coincidence circuit, so that only the activity common to all channels—namely that of the heart—is accepted and used to pulse a transmitter Although muscle-action potentials are large and there must be some movement of the electrodes, the transmitter will produce a clean pulse for each heart beat, at rates up to 100 beats a minute The complication of three gating circuits is well worth while, because low-frequency filters and tuned circuits are unnecessary No form of integrator was fitted to the prototype C T, the rate being determined by counting the transmitter pulses as heard over a loud-speaker, or as displayed on a cathode-ray tube The pulses may be recorded on tape, together with a commentary on the activities of the subject A miniaturised version of the transmitter, small enough to go in a soldier's pack, is under development There is no reason why this particular instrument should be confined to cardiotachometry—various other physiological measurements, such as body-temperature or vapour pressure, could be transmitted—and it could be of great value in studies of industrial fatigue

ELECTRONIC CIRCUITS AND EXPLOSION RISKS

During an investigation of heat-production in electronic apparatus, Shaw[11] found that the glass envelope of a miniature valve, dissipating 10 or 12 watts, might be as hot as 250°C, and that temperatures of 150°C to 180°C are customary when the valve and its associated equipment are enclosed in a case whose cooling arrangements have been arrived at by the usual rule-of-thumb methods As the Report of the Working Party on Anæsthetic Explosions[12] recommended that 149°C should be the maximum temperature of exposed surfaces in potentially explosive atmospheres, there is a risk attached to the use of electronic instruments in such surroundings Heavy, gas-tight instrument-cases are not satisfactory, temperatures in them are bound to be high and circuit components deteriorate rapidly, and stability—an essential in high-gain amplifiers—suffers accordingly Since most valves operate at anode potentials of 250 volts or more, another source of danger, especially with capacitative circuits, is that a break in the high-tension line or the opening of a switch may produce a vicious arc even though the current flowing may be no more than a few milliamps

TRANSISTORISED CIRCUITS

Junction transistors are small, remain cold, work at low voltages, and draw minute currents circuits using them are inherently safe in the presence of flammable or explosive vapours and gases The first "transistorised" C T was described by Molyneux[13] three years ago, and he has since published details of an improved model[14] Although carrying out many of the same functions, valves and transistors are not directly interchangeable, and the amplifier of Molyneux's instrument differs from that of a valve-operated C T, since transistors are particularly sensitive to changes in ambient temperature, a compensating circuit has to be included The amplifier has a pass-band of 10–14 cycles a second, and stringent tests have shown that "double counting" will take place only when the subject carries out really energetic movements Because of the slow response of the integrator—a matter which will be discussed later—the C T incorporates a transistor oscillator to produce an audible signal for each heart beat, so that the onset of any irregularity may be detected immediately Electrical interference is kept to a minimum by the use of a wooden case and a wooden chassis A small dry battery is enough for forty hours' use before any sensible change takes place in the calibration The instrument has a high input impedance—80 kilohms—so that it can be used in parallel with a standard electrocardiograph without affecting the appearance of the trace

FŒTAL HEART-RATE RECORDING

The recording of the fœtal heart-rate presents some special difficulties, and what is believed to be the first leaflet recommends suitable passages from the Bible for those who seek peace and tranquillity

Occasional Survey

CARDIOTACHOMETRY

ONCE the thermionic-valve amplifier had been applied to the electrocardiograph, the era of the delicate and temperamental string galvanometer was almost over Amplifiers have improved and new methods of recording the electrocardiogram (E C G) have evolved, but the major advances of the last two decades have been clinical rather than technical, so it may seem surprising that instruments for the accurate recording of the heart-rate are only now emerging from the laboratory stage Stable high-gain amplifiers have been available for some time, but those with a sufficiently large signal-to-noise ratio are a development of the past five or six years

In 1952, Boyd and Eadie [1] published details of a cardiotachometer (C T) for use with decerebrate or anæsthetised animals, some of the more interesting features of its design have already been noted [2] Two years later,[3] the same workers described a new instrument for continuously recording the heart-rate of a patient either lying at rest in bed or else carrying out controlled exercises while standing Boyd and Eadie found that, in spite of the experience gained with the earlier C T , many new difficulties arose, and in their article, which includes a valuable list of references to earlier work, they discuss the various means adopted to overcome them

Essentially, a C T consists of a transducer which produces an electrical signal for each heart beat, this signal, the pulse wave, which may come from heart-sounds or the E C G , is fed to a wave-shaping circuit which provides an impulse of constant amplitude for each beat A further circuit integrates these impulses with respect to time and supplies the necessary output for a visual indicator—usually a specially calibrated voltmeter, or else a graphic recorder

TRANSDUCERS

There are many different forms of transducer, each with its advantages and drawbacks The impedance plethysmograph [4] [5] measures the change in impedance to radio-frequency current in a limb as the amount of blood varies between systole and diastole, and could furnish the required input to trigger a wave-shaping circuit However, since muscle movements affect the blood-volume between the electrodes, the impedance plethysmograph is of little value unless the subject is at rest

An adaptation of the photoelectric oximeter, first described by Millikan,[6] could be used—as also could a photoelectric cell operating with light of a suitable wavelength reflected from the skin Unfortunately, the oximeter is heavy and uncomfortable, and even if it were possible to use the tiny photo-transistors now obtainable, its utility would be restricted since the cases in which the C T is most needed are often those in which the output of the heart is greatly diminished, either from disease or during some surgical procedure

A microphone on the chest wall or on the side of the neck will give a large enough output, but, once again, its use is confined to patients at rest, because extraneous noises and sounds from the friction of clothing add many artefacts to the signal The thermionic transducer is more sensitive than the conventional microphone, and its signal would need less amplification, but it is costly and equally affected by unwanted sounds

ELECTRICAL INTERFERENCE AND ITS ELIMINATION

In man, the R wave of the E C G in lead II has an amplitude of between 0 4 and 2 3 millivolts (mV)—about ten times that of the P wave, which Boyd and Eadie used in their original C T —and can, under ideal conditions and after pre-amplification, provide an excellent triggering signal for a wave-shaping circuit However, when the subject moves about, the sharp spike of the R wave disappears in a mass of interfering potentials of various frequencies and amplitudes The wave-form as actually picked up includes the E C G itself, muscle action potentials with an amplitude of 10 mV or more, 50 cycles a second interference of up to 750 mV from electrical wiring, and, perhaps, diathermy and X-ray interference of any frequency and amplitude In addition, there are various zero frequency potentials derived from electrochemical action in or under the skin or in the materials of the electrodes, and from the skin of anyone touching the patient This sounds a formidable list, but as Parker et al [7] showed a few years ago, much of the interference can be eliminated by use of some of the recognised " tricks " of the electronics engineer In their radio-electrophysiolographograph they used a small frequency-modulated transmitter, the signal from which was picked up by a receiver equipped with a number of analyser filters It was necessarily a complicated instrument—though ideal for the investigations for which it was designed—and its proper functioning depended a great deal on the electrostatic condition of the atmosphere

A capacitance-coupled amplifier is unaffected by zero frequency potentials, trouble may arise from the amplifier " blocking " from voltage transients arising from movements of the electrodes, but this can be minimised by careful electrode design Boyd and Eadie [3] found that screening and filtering would eliminate most of the other interference, but that muscle activity was still troublesome In the first version of their human C T they used a selective amplifier, resonant at 6 cycles a second, unfortunately, the circuit was unstable at this low frequency The second C T incorporated a triode phase-shift oscillator which proved both simple and reliable It is possible for the T wave to trigger this, or any other circuit with a good response at about 6 cycles a second, and so cause " double counting " If, however, the wave-shaper is provided with the electronic equivalent of the refractory period of a nerve, it can be rendered

Ministry of Health, the Agricultural Research Council, the Medical Research Council, the Government Chemist's department, the Board of Trade, and the Nature Conservancy The advisory committee recommends whether or not a substance should be included under the Agriculture (Poisonous Substances) Regulations, and, in the case of substances not included, it may make recommendations for the safety of users and invite manufacturers to include on their label the appropriate voluntary precautions The consumer is protected by recommendations regarding dosage of material to crops and stored products, method and frequency of application, and the interval between application and harvesting The risks to livestock and wild life are also considered

Hazard to the consumer is hard to assess It is practically impossible to prove that any substance is harmless, and the committee must decide whether a few parts per million of a toxic substance ingested daily for a lifetime by a whole population is likely to harm individuals or the population as a whole It is not surprising that the committee is content to say that, subject to conditions described in the recommendations, a material " should present no hazard to consumers " So far, no cases of illness have been recorded as a result of eating food treated with any pesticide according to accepted methods, but accidental poisoning occurs from time to time For instance, Davies and Lewis [1] reported that a number of people ate bread made from flour contaminated during transport by 'Endrin', a chlorinated hydrocarbon type of insecticide In the U S.A dicophane (D D T) has been detected in the fat of persons who had had no occupational exposure to this substance, which was apparently ingested in food There is no evidence that the presence of as much as 20 parts per million in the fat gives rise to any symptoms [2] Whether it is desirable to treat food with substances which can accumulate in the tissues of man and animals is another matter, and must be assessed in relation to the benefits of the increased food production that has resulted from the use of pesticides

It is easier to advise on measures for protecting persons using pesticides, and where necessary to enforce these by legislation The Agriculture (Poisonous Substances) Act, 1952, was designed to make compulsory certain provisions for the protection of persons using toxic chemical substances in agriculture and horticulture

The committee has recommended the addition, to substances scheduled under the Act, of fluoracetamide formulated at a strength greater than 1% active ingredient, and the alkali arsenites With regard to the latter substances it recommends that the Agriculture (Poisonous Substances) Regulations should be amended to prescribe that workers who handle potato plants which have been sprayed with arsenites within the preceding ten days must wear suitable protective clothing [3]

Organo-mercury compounds used as aerosols in greenhouses already come under the regulations The current recommendation with regard to organo-mercury dry-seed dressings may need to be amended The committee has agreed that organo-mercury compounds with a vapour pressure not greater than that of ethyl mercury chloride when used alone, or as a component of dry-seed dressings, need not be included in the regulations Ethyl mercury chloride is approximately as volatile as metallic mercury [4] It is therefore volatile at room temperature, and the volatility will increase as the temperature rises The maximum allowable concentration of inorganic mercury is accepted as 100µg per c m of air, and Ahlmark [5] recommended that the upper limit for organo-mercury compounds should be 10 µg per c m In the case of the dry dressing of seeds a potential risk exists, not only from vaporisation of the organo-mercury compound, but also from the presence in the working atmosphere of dust of small-particle size It is difficult to believe that the concentration present in the atmosphere will be less than 10 µg per c m Poisoning by organo-mercury compounds causes selective damage to the central nervous system which may lead to permanent disability or death In the reported cases the most serious effects have resulted from contact from ethyl or methyl derivatives, and laboratory workers as well as those engaged in the manufacture and use of these materials have been affected [6]

Seed-dressing stations where organo-mercurial dusts are used are subject to the regulations of the Factories Acts (1937) and protection of workers in these places should be adequate, but some seed-dressing is done in less favourable conditions If the committee's advice to agricultural workers handling seed treated with organo-mercury dry dressings is followed, the hazard should be slight, but since voluntary precautions are sometimes ignored it may become necessary to make the precautions obligatory In the recommendations for protection of consumers, the suggestion that " sacks which have contained dressed seed must be well shaken " is surely bad advice unless the person doing the shaking and those in the vicinity are adequately protected

Antibiotics are being used on an increasing scale for food preservation Recommendations are made for one of these, 'Griseofulvin', for which no special precautions for the operator appear to be necessary

The experience of one employer showed that in men using 'Diazinon', an organo-phosphorus compound of low toxicity, the plasma-cholinesterase decreased even though they wore protective clothing which included gloves Investigations suggest that, possibly because of solvents or other additives, gloves may not remain impervious to organo-phosphorus compounds, and enough may be absorbed through the gloves to depress cholinesterase activity

Smallpox in the Wirral

When smallpox was diagnosed in the boy aged 2 living in New Ferry,[7] his grandmother and sister were vaccinated on April 14 The grandmother, who had been vaccinated only in infancy, had a primary take She became feverish on Monday, April 21, and on the Wednesday evening a discrete palpable macular rash appeared on her trunk and limbs The rash became morbilliform on Thursday, and papules appeared on the limbs on Friday The sister, who had not been vaccinated before, also had a primary take She became feverish on Tuesday, April 22, and on the Friday, when her temperature settled, a few papules appeared on her limbs, forehead, and neck Neither patient is generally ill, but both have been admitted to New Ferry Smallpox Hospital, smallpox virus has been isolated from scrapings from the lesions The Indian seaman at the hospital has recovered, except for a few lesions on his feet thought to be infective

Arsenic and Lead on Apples

Public-health inspectors at Coventry recently found traces of lead and arsenic on the skins and stems of two batches of apples from the Lebanon [8] The contamination is thought to have been caused by a pesticide spray The Ministry of Health reports [9] that the trade has cooperated in safeguarding against this hazard in apples from certain Mediterranean and Middle East countries by having the contaminated fruit washed, but some such fruit may have escaped detection " The elementary hygienic practice of washing all fruit before eating affords adequate protection from any hazard to the consumer peeling and coring provide an additional safeguard " fœtal C T was described by Smith[15] about a year ago Heart-sounds had to be relied upon, as it proved impossible to separate the electrical potentials of the maternal heart beat from those of the fœtus Smith admits that the instrument is not perfect, but his results were encouraging, as it proved possible to record the fœtal heart-rate over a number of hours and even during the final stages of labour A sensitive vibration pick-up was strapped to the abdominal wall over the point where the fœtal heart-sounds could be heard most clearly There was no interference from the heart-sounds of the mother, and, in twin pregnancies, it proved easy to pick up an interference-free signal from each fœtus The output from the microphone is fed to an amplifier with a voltage gain of 10^6 and a pass-band of 60–80 cycles a second, this amplifier has special characteristics to discriminate against digestion noises and uterine souffles The heart-rate is displayed as a trace on a graphic recorder

The only serious interference came from clothes and blankets rubbing against the microphone, the high noise levels of hospital wards and labour rooms gave no trouble, and any spurious pulses caused by fœtal movement were too short in duration to affect the instrument Interference with the record from movements of the patient during labour was unavoidable, but careful supervision enabled these artefacts to be recognised

Although not strictly a cardiotachometer, as it does not include any form of integrating circuit, a fœtal phonocardiograph described by Dewhurst and Mainland[16] has several interesting features intended to deal with a specific problem—namely, the determination of the presence of the fœtal heart sounds As Wood[17] pointed out a few years ago, the fundamental frequency of the fœtal heart-sound is about 16 cycles a second, varying proportions of higher harmonics are usually, but not always, present[18] Since the fundamental frequency is below the limit of audibility, the output from the phonocardiograph is fed to a graphic recorder, though a headphone responding to the higher harmonics is provided for placing the microphone An integrator was thought unnecessary as the phonocardiograph is intended purely for diagnostic purposes after the twentieth week of pregnancy The fœtal heart-sounds are picked by a crystal microphone, loaded to give a peak response at 25 cycles a second, in contract with the mother's abdomen The high-frequency response of the amplifier, which has a usable gain of 2×10^6, is purposely limited to render it insensitive to outside noises The fœtal heart-rate of 120–160 beats a minute falls just within the limits of the upper frequency response of a slightly modified commercial E C G recorder

INTEGRATING CIRCUITS

The slow response of an electronic integrator, while sometimes adequate for physiological research, is often inconvenient for clinical use where an immediate indication of a change in heart-rate can be of vital importance Manzotti[10] suggests that an accuracy of ±2 beats would be reasonable in an integrator in which 30 beats would be needed to reach 90% of a variation consisting of a sudden jump in the heart-rate from 60 to 120 beats a minute But when other physiological phenomena must be correlated with the heart-rate, the circuit must record it instantaneously, and must therefore give, at every beat, a signal proportional to the reciprocal of the time interval between that beat and the preceding one In Manzotti's C T, the computing circuit releases a constantly delayed signal for every R wave This signal displays, on the Y axis of a cathode-ray tube, a potential that decays hyperbolically and is therefore proportional to 1/time The electron beam is cut off except for the time between the R wave and its delayed signal, just at the end of the R-R interval, hence a dot can be recorded photographically which—provided the delay has been properly chosen—has an ordinate proportional to the heart-rate, as computed on the R-R time interval

At about the same time as Manzotti, Wyatt[19] described a heart-rate meter which could register 99% of the true rate in three seconds He has lately produced an instrument with an even better response[20] The heart-rate is indicated on a specially calibrated microammeter and is accurate to ±2% This performance has been attained only at the expense of considerable complexity which would probably preclude the use of the instrument outside the laboratory

Technical finality has clearly not yet been reached in C T design The gated amplifier of the Clothing and Stores Experimental Establishment design seems to have great promise, especially if it could be followed by an integrator with a quick response giving a visual numerical display on the lines of various scalers and counters now produced commercially for counting atomic disintegrations

Public Health

PESTICIDES

NEW pesticides may be poisonous, not only to persons engaged in their formulation, manufacture, and application, but also to the public who consume products treated with them The problem of protection has been dealt with by different methods in different countries

In the U S A the Food and Drug Administration (F D A) is responsible for advising manufacturers about new substances, including pesticides, and establishes limits for the amounts of any added material which may remain in food as residue from spraying or other treatment It has power to seize and examine food to ensure that regulations are not infringed In Great Britain control depends largely on voluntary cooperation between the pesticide industry and Government Departments

Negotiation between the industry (represented by the Association of British Insecticide Manufacturers) and the Ministries of Health and of Agriculture, Fisheries, and Food has led to agreement on a procedure whereby the manufacturer or distributor of a new pesticide, or of a new formulation of a known pesticide, gives notice voluntarily of the intention to market the new product, together with the fullest possible particulars of its properties and use, so that Government Departments may advise on measures to protect both workers and consumers The resulting recommendations do not have the force of law

The data are considered by an advisory committee (set up by the Government in 1956) and a scientific subcommittee, which comprise representatives from the Ministry of Agriculture, the Department of Agriculture for Scotland, the Department of Health for Scotland, the

Letters to the Editor

CEREBRAL PALSY

Sir,—Your leader of April 19 raises a number of questions, the most fundamental of which is that of definition To define " cerebral palsy " is important, not only because people with it have " certain needs in common ", but as an essential preliminary to research and exchange of information It is also essential that any definition is acceptable equally to neurologists, pædiatricians, and others and that they adhere to it in discussing the topic.

There are certain points which your definition of " cerebral palsy " as " a congenital motor deficiency that is not progressive " does not make clear Are we to include " motor deficiency " caused by congenital lesions of the cord, nerves, muscles, bones, and joints? Are we to exclude disorders acquired in the neonatal period, such as those following severe jaundice of the newborn? Is the " motor deficiency " always, or even frequently, congenital—that is, present at birth? Is the " motor deficiency " never progressive? (What is not progressive is the lesion, its signs and symptoms change with development as emerging functions interact with older dysfunction) Is " motor deficiency " appropriate for cases which essentially show unwanted movements?

To define " cerebral palsy " cannot be easy, for the cases it includes are not all identical In trying to arrive at a useful definition of cerebral palsy certain points need to be considered

(1) It is a palsy or *motor disorder*

(2) It is the result of a lesion of the *brain*

(3) Only disorders resulting from *non-progressive lesions* are to be included

(4) The damage of the brain may be from intrinsically or extrinsically caused development disorder (occurring in fœtal life or after birth) or may be perinatal, paranatal, or postnatal in origin

(5) The moment of birth as a criterion in definition has little usefulness, for birth is only an incident in the long course of prenatal and postnatal development of the nervous system What is important is the stage of development of the child at which the damage responsible for the motor disorder occurs, the word development here implying that of the intellect and personality as well as of the central nervous system.

During the past year a number of interested people have met at the Little Club to discuss a memorandum on the terminology and classification of " cerebral palsy " The memorandum is not final but it seems worth while to set out below the definition of " cerebral palsy " arrived at together with its explanatory footnotes The participants in the discussions were Dr N S Alcock, Dr J Bates, Dr E A Carmichael, Dr J Crosland, Dr P R Evans, Dr M C Joseph, Dr M J McArdle, Dr D McDonald, Dr I C K Mackenzie, Prof A A Moncrieff, Sir Charles Symonds, and the undersigned

London, S E 1

R C Mac Keith
P E Polani

DEFINITION OF " CEREBRAL PALSY "

In the present state of our knowledge the term " cerebral palsy "[1] is taken to imply a persisting qualitative motor disorder[2] due to non-progressive[3] damage[4] of the encephalon[5] occurring before the growth of the central nervous system is complete Because the cases it includes are not all identical from clinical, ætiological, and morbid anatomical aspects, the term " cerebral palsy " is not an exact one In scientific usage, as we learn more about each, the names of individual disease entities within the group should be used Meanwhile, however, for research purposes the term " cerebral palsy " is useful in the study of a group of conditions often of obscure origin affecting the brain and arising in early life. A strict definition is necessary and should be adhered to if the term is to be used for research and in the exchange of information

On the other hand, in common usage the term has administrative usefulness and a practical value largely because the affected children often have certain special motor, intellectual, and emotional difficulties in common and so have certain special therapeutic and educational needs The effect on a child of a motor handicap of cerebral origin, present from very early in his development, is very different from that of a similar disorder occurring later For the purposes of definition a time limit has to be fixed The definition of " cerebral palsy " therefore proposed is

> a persisting qualitative motor disorder appearing before the age of three years, due to a non-progressive damage of the brain

Sir,—In the two articles and the leader in your issue of April 19 only the briefest mention is made of the place of surgery in the treatment of limb deformity Out of some 10,000 words less than 200 were used to discuss surgical treatment and these mostly to describe a single case of an operation for flexion contracture of the knees

The repeated disappointments which followed operations in the past and in particular the misadventure of Royle's sympathectomies caused such gloom to surround the value of surgery for the correction of limb deformities in cerebral palsy that there are today undoubtedly many patients of good intelligence and personality who struggle about with grotesque skeletal deformities such as would not be tolerated in almost any other disease

Dr Palmer states that he has no doubt that " there is a place for surgery in the adult spastic, but this must be very carefully considered beforehand " But the need for careful consideration of an operation should not act as a bar The planning of an operation is no problem special to cerebral palsy, but is called for in the judgment of any reconstructive operation, whether it be for hallux valgus or for the improvement of an osteoarthritic hip-joint

There is no doubt that much can already be done by operations to assist many patients suffering from limb deformities consequent upon cerebral palsy, and much can be learnt by carefully planned and staged procedures, but this is not the place to discuss these in detail

What is now urgently needed is a *systematic* programme to study the possibilities and limitations of surgical methods for the relief of limb deformities in cerebral palsy, which could in time produce results comparable to those achieved in dealing with the effects of poliomyelitis It is to be hoped that the programme of vaccination against poliomyelitis will release the surgical skills and time for this purpose in the not too distant future Some start should now be made

London, W 1

Lipmann Kessel

---

[1] The adjective infantile before " cerebral palsy " is not considered to be necessary as the term has no place in the neurology of adults

[2] This excludes such quantitative disorders of movement as might be met with in mental defectives

[3] The clinical evolution with the passage of time seen in cases of " cerebral palsy " has usually been explained by nervous system growth and maturation with the resulting emergence of new functions and their interaction with old deficits Some workers think this explanation inadequate and suggest that some of the changes in clinical findings could be ascribed to progressive pathological lesions

[4] The damage of the brain may be from intrinsically or extrinsically caused development disorder (occurring in fœtal life or after birth) or may be perinatal, paranatal, or postnatal in origin

[5] The brain, that portion of the central nervous system above the foramen magnum

In England Now

A Running Commentary by Peripatetic Correspondents

I HAD prided myself on being perhaps the first doctor in Britain to use nylon syringes They proved invaluable and the breakage-rate dropped to zero almost overnight The pleasure of having syringes which bounced was never-ending Now I may prove to be the first to give them up

At the end of my new secretary's afternoon duties she left the place tidy for evening consultations, with one nylon syringe on the steriliser and five inside Those who, a few hours later, met all the dark smoke filling the rooms and corridors thought at first that the house was on fire The five syringes have gone—are nowhere But the inside surfaces of the steriliser and the edges of its lid bear a thick hard coating of glossy black The nearby walls and ceiling look even more off-white than before For strength and tenacity let me recommend distilled nylon Hours of scrubbing and every solvent the dispensary, the kitchen, and even the garage could produce have made a quite tiny impression on the dark layer My secretary and I reckon that with diligence and detergents the steriliser may be clear by Christmas

My unhappy wife cannot rid our house of its new odour It reminds me of those window-jammed homes I hate to visit, the sort of house into which I do not take my hat lest I have to put it down on one of its uninviting surfaces The modern-minded women among my patients say that they are familiar with the new odour of the professional rooms Yes, as they give their little disgusted domesticated sniffs, yes, they had met it when the iron was too hot for their nylon frilleries The material under the iron just disappeared, or rather was converted into slight stickiness of the iron plus a smell I have even been told of a girl who wore her nylon nightgown too close to a fire and suddenly, without flame, found herself naked

My syringes have gone, but oh, how their memory lingers on!

Clearing out the attic I found some old medical objects of my grandfather's, and rather than throw them away I offered them to a dealer

After handling one in a cursory manner, his speculative eyes slowly looked me up and down "You are a medical man, I presume?" I nodded agreeably and awaited identification of the article He wheeled round, stuck his head into the hatchway, and shouted, "Did you hear that, Bert? Medical gentleman here never heard of a fleam—and a three-bladed one, too!" He was answered by a raucous Cockney yell of derision from the vaults below Having thus drained me of confidence, he continued briskly "Now, sir—these articles—kindly name your price" I ventured 2 guineas After all, my Green Line fare to Church Street was *7s 6d* "I'm afraid you are wasting our time, sir *17s 6d*," he snapped and made to move away I disliked the thought of approaching another dealer, and, after I had pocketed the handful of silver, he became more expansive Slowly sucking his yellow teeth, he sighed "Of course, I shall have to clean them up and another nuisance, you've lost the locking nut for the Tribulcon Bert," he roared, "fix this hinge and tell me if it's a Tribulcon or an Alphonsine"

My ignorance apparently offended him, but taking a firm grip on his patience and speaking slowly, he explained "The early Napoleonic bullet-extractor was called an Alphonsine after some surgeon-general The Tribulcon was a bit earlier Both damaged the tissues more than the bullet Now, I believe this here is a Freeke's tourniquet of about 1820—you've ruined the cog-and-wheel mechanism—and the handle to tighten the band is very loose They were never satisfactory I ought to ask you for my money back This sort of blow-lamp is an early antiseptic steam-spray producer" My heart sank as he exhaled on the name-plate and, with a vigorous rub, disclosed with fearful clarity *for Prof Lister by J Gardner instr mkr Edin*

"What a pity you haven't got the scarifier," he sighed, as he prised open the small silver box from which two rusty needles fell out "It could be a Jenner—probably not an original, though *E Jenner, Sgn, Berkely*, looks faint and genuine enough" He smiled whimsically as his eye caught the fleam again and he was just about to laugh in my face when he braced himself to say, in a censorious tone, "Junk—sheer junk! Top prices paid and I still have to make an honest living" He poked at the heap in mock reproach with a dirty fingernail "Oh well, I suppose the private collectors and the museums will fight for them" His tone was tinged with triumph and I was halfway through the door before he remembered to cry, "Have you any more? Top prices" But I waited no longer and, retiring to the nearest espresso, pondered over a cup of black coffee on my amazing ignorance

* * *

Your peripatetic tale about the lost bicycle pedal reminds me of my failure in World War I to interest the powers that be in the great saving of steel that could be effected by providing members of mounted regiments and others wearing spurs—e g, G O C London Command and some others of the Military Police—with only one spur instead of two The argument, based on anatomy, is of course that if you get one side of the horse going in the right direction, the other side of the horse will go the same way And what's wrong with that, I ask you? Alas, I couldn't induce any general to think that he thought of it first And so it wasn't done

* * *

Pop was moved into the sideward of the female surgical ward with certain misgivings It had been used for men before but each occasion had produced such a violent reaction in the sister that we had sworn never to repeat the practice Pop, also, was probably not going to be the easiest patient to nurse, for he was to have his remaining leg amputated because of senile gangrene

Surprises were not long in coming The next morning on the round we were told that he was "a dear" The afternoon before he had asked the librarian for a book by "that Dickens chap", and since then he has read several of this author's larger tomes, which by the look of them had not been off the shelf for many dusty years The delay in healing of his stump, while not being surgically satisfactory, has proved so socially to the sister—"The first man I've had in there whom I can tolerate"—and his protracted convalescence has helped his family through the recent cold spell Mum comes in with a cheery "Well, Dad, how are you today?" and the interchange of news goes on for about five minutes After this the comfortable armchair by the fire is amply filled and Mum dozes off leaving the rest of the conversation to her daughter Wednesdays, Saturdays, and Sundays are the best days because really it does take longer than twenty-five minutes to get warm right through

Letter from a mother-to-be to her G P

During the past few months I have consulted many experts about the safest way to have a baby *Some say this, some say that.* Some induce, some wait Some are for Cæsarean, some are for forceps, some are for trial Some weigh Some give salt, some say it's poison Some transfuse, some don't Some say it's dangerous to have a baby in hospital because of sepsis, others that it is dangerous to have a baby at home because of lack of asepsis What *is* a poor woman to do?

The G P's reply

Get a good midwife to hold your hand and rub your back—that *is* essential

Thank God my rhesus-negative wife produced our four yellow babies 13 to 20 years ago—in ignorance of what the experts think is the "safest way" Either she or I would have died of anxiety, and I'm not sure we should now have four rather nice children

As regards malaria, the present anti-larval and hygienic measures have been so widely applied, aided by the much improved methods of drug prophylaxis and treatment, that a state of affairs has been created where the malarial anæmia, with which I used to be so familiar, exists no more. I remember in particular a group of Arabs from the Hedjaz in hospital in Cairo in 1916 They were one and all suffering from such a severe form of anæmia of the pernicious type that they became the subject of hæmatological studies by the contemporary blood experts In some few the spleen was palpable

However, after careful scrutiny of their blood by the thick-film method, scanty crescents of the subtertian parasite were found in all and they recovered after long-continued quinine therapy

London, W 1 PHILIP MANSON-BAHR.

ABSENCE FROM WORK ON A MEDICAL CERTIFICATE

SIR,—I write to support the statement of Dr Gough (April 19) He asks employers to accept a written statement from employees concerning their sick absences rather than demanding a doctor's certificate.

This company pays all clerical and factory employees for absence due to sickness Twelve months ago we dispensed with doctors certificates for any absence of less than four days On return to work after illness employees now report to the nurse in the works surgery and sign a declaration that their absence was due to genuine sickness

This scheme, which is greatly appreciated by the employees as well as by the local doctors, has in no way been abused and the absence due to sickness has not increased.

PENICILLAMINE AND DIMERCAPROL

SIR,—I have read with interest of Dr Aposhian's studies (April 19) on the relative efficacy of B.A.L and penicillamine in protecting rats against mercuric-chloride poisoning He criticises my work on the relative activity of these two compounds in mobilising copper from patients with Wilson s disease [1] on the grounds that the two drugs were not given in equimolar amounts or by the same route.

May I suggest to Dr Aposhian, first that penicillamine and B.A.L should not be compared on a molar basis but in terms of available sulphydryl groups—i.e., one molecule of B.A.L (M.W. 124) to two molecules of penicillamine hydrochloride (M.W. 205 2), approximately 1 unit of B.A.L to 3 3 of penicillamine HCl. On this basis he will find, if he reads my paper again and carefully, that cases 3, 4, and 6 were given approximately comparable doses of these two compounds. In each case the response, in terms of increased copper excretion in the urine, showed that the penicillamine was a very much more powerful cupriuretic agent than B.A.L.

Second, in clinical practice, as opposed to animal experiment, it is ridiculous to limit the usefulness of a new treatment by scaling it down to the limitations of the old. To compare the activity of B.A.L and penicillamine in man why reduce the dose of the latter and give it parenterally, why not raise the dose of B.A.L so that it is comparable to the maximum tolerated dose of penicillamine (around 4 g) and give both by mouth? The procedure would be just as logical

Finally I suggest that Dr Aposhian has tumbled into the old pitfall of trying to argue direct from the experimental animal to man. From his results with mercuric-chloride poisoning in rats he is attempting to draw valid conclusions about copper intoxication in man, a hazardous procedure. From the patient's point of view the usefulness of a drug can be decided only in terms of the response obtained to the maximum tolerated dose.

PLASTIC BAGS FOR STORING AND TRANSFUSING BLOOD

SIR,—The article by Dr Dudley and his colleagues (Feb 8) is of great interest to those of us in the United States who have been concerned with the development of improved blood-transfusion equipment. The studies reported undoubtedly represent a sincere effort to compare plastic and glass containers, and at first glance the conclusion that red cells are no better preserved in plastic than in glass seems to be supported by the experimental data.

I feel it my duty, however, to point out that the experiments reported did not truly compare the preservation, during refrigerated storage, of red cells collected in plastic bags and glass bottles

The solution used in the bottles (A.C.D formula A, *U S.P*) was transferred from the plastic bags to the bottles, presumably shortly before collection of blood This solution was autoclaved in the plastic bags and had been exposed to the plastic up to the time of use. It was not autoclaved or stored in the bottles in which the blood was collected. Thus the survival experiments of the bloods collected in the bottles cannot reflect deleterious effects on red cells of changes taking place in the solution on long exposure to glass There is increasing evidence that an interaction between contained solutions and glass surfaces does take place under such conditions

On Oct. 12. 1957, a conference on the Deterioration of Parenteral Solutions was called by the National Research Council in Washington, D C. At that conference a report on particulate matter in intravenous fluids was presented from the Walter Reed Army Institute of Research Using an instrument primarily designed for red-cell counting, it was found that solutions of saline, dextrose, and dextrose plus saline, dextran, and A.C.D , which had been stored for varying periods of time, registered particle-counts up to a million per 100 ml. These particles were found to be silica Precipitation of fibrin from whole blood by means of finely divided glass is often used. Such a reaction may well account for the frequent finding of " sludging " of red cells in blood collected in bottles. This is destructive to red cells of stored blood, as shown by the elevation of the hæmoglobin content of plasma

In contrast the A.C.D solutions processed in plastic bags had particle counts of less than 10 000 per 100 ml. Widespread experience has shown hæmoglobin levels of plasma of blood collected in plastic bags to be consistently lower than that of blood collected in glass

It may therefore be truthfully said that the experiments reported merely demonstrate the excellent stability of A.C.D solution autoclaved and stored in plastic containers

No claim has ever been made that A.C.D blood collected in plastic bags could be used routinely beyond the 21-day limit prescribed by the Minimum Requirements for Human Blood (Citrated) [1] of the National Institutes of Health. In the article by Walter [2] referred to by Dudley et al in eleven experiments the post-infusion survival of the red cells of blood stored 21 days at 4 C ranged from 66 to 93%, averaging 84 %, certainly a very safe and satisfactory level, even for multiple transfusions

"THESE DYING DISEASES"

SIR,—With the first few words of Dr Vickers' letter (April 19) I agree Mr King's article was timely and should be taken to heart by those who are responsible for anti-venereal arrangements in this country To those with sufficient knowledge to understand the implication of the facts Mr King has brought to notice, the prospects of combating venereal disease in this country must appear indeed gloomy He has shown a steady rise in antibiotic-resistant gonorrhœa and of non-gonococcal urethritis, which is doubtless becoming increasingly resistant to the antibiotics being, often blindly, lavished upon it And all these diseases are being spread at a greater rate than formerly by reason of the greater invasion of the country by immigrants

These alone are sufficient to merit grave concern As regards syphilis, Mr King has pointed out a possible fallacy in the inference to be drawn from the figures relating to new cases seen at the clinics when he says

> 'The main antisyphilitic remedy is used freely for many other conditions Possibly this helps to prevent the late serious effects of syphilis, but it may suppress information which would help us to estimate the extent of the problem "

We may, in fact, be in a fool's paradise in respect of this disease

With the remedy suggested by Dr Vickers I emphatically disagree, and that is on the basis of half a century's experience of the problem from most angles—laboratory, clinical, social, and administrative, both local and general As adviser on venereal diseases to the Ministry of Health, I saw, in the venereal-diseases treatment centres working under the Local Government (Venereal Diseases) Regulations, these diseases treated by general physicians, surgeons, gynæcologists, dermatologists, genitourinary specialists, and other kinds of specialists and can say without any hesitation whatever that in those hands, however skilful they might be in their own branch, with very few exceptions the result (so far as ridding the patients of their infections and stopping their danger to the community was concerned) was bad I have often wondered why these specialists in other branches accepted charge of venereal-disease clinics, and have sometimes remarked, at the end of a session which the medical officer spent seated at a desk writing " Rp " on successive case-sheets, that he must find it very boring Dr Vickers contrasts venereology with specialties concentrated on particular parts of the body and seems to think there is something unnatural about it, but what about tropical diseases, which are analogous to venereal diseases in being like one another in the circumstances of their contraction?

Dr Vickers sees little likelihood in young men taking up venereology He is probably correct in the present circumstances, particularly when those responsible for the arrangements for dealing with what is really a serious national problem take such a superficial view of the position as to talk of " these dying diseases "

London, S W 1 L W HARRISON

SIR,—The letter by Dr Vickers about the future of venereology seems to me to have been based on a misunderstanding of the fundamental argument in Mr Ambrose King's article There is, as far as I am aware, no evidence that the service is " slowly but inevitably disintegrating " In 1956, 98,212 men and women attended the venereal-disease clinics of England and Wales for the first time The fact that so many people should seek advice and help does not appear to indicate that the service is disintegrating

With regard to the recruitment of young doctors, the major problem here is surely one of confidence in the future of the service If consultant posts which become vacant are not filled or are filled with a reduction in the number of sessions it will obviously be difficult to persuade competent young men that their future lies in venereology In some areas the spectacle of consultant work being carried out by S H M O s and even persons who have no special training in the subject is hardly encouraging The solution of the recruitment problem lies in the hands of the regional boards and the boards of governors of the teaching hospitals Only if posts are filled by trained venereologists when they become vacant will entry into the specialty be stimulated and the future of the service assured

Patients attending venereal-disease clinics have many special problems, both physical and psychological, and special training and experience is needed to handle them When those who have or think that they have venereal diseases are dealt with by persons without adequate training and interest in the subject, they are frequently mismanaged

London, W 8 R D CATTERALL

HOOKWORM AND ANÆMIA

SIR,—The communication on hookworm and anæmia by Dr Meiklejohn and Dr Passmore in your issue of April 19 is very opportune, for I am one of those who are in mild disagreement with some modern high-powered hæmatologists who would ascribe most forms of anæmia in the tropics to dietetic causes, thereby trying to debunk the role of the ancylostome and the subtertian malaria parasite as the main causes I feel certain that they could not have done so had they lived as long as I have and been with me fifty years ago

There is no doubt that there is a racial factor The Fijians, who are heavily infected with hookworms (27 8%[1]), seldom, if ever, suffer from anæmia—and this has been verified by Wills and Bell[2] On the other hand, the Indians who are domiciled in Fiji frequently do, and I saw many at necropsy there in 1910 Similarly in Ceylon, in 1912, I performed such an examination in a Tamil where death was due to intestinal hæmorrhage from petechiæ throughout the small intestine This specimen, together with the adherent ancylostomes, was brought back to the museum of the London School of Tropical Medicine

There was another which springs to mind in a young Tamil labourer who died from acute heart-failure on climbing a hill, and in him, too, the hookworm anæmia was so severe that his hæmoglobin was about 15%

PLASTIC BAGS FOR STORING AND TRANSFUSING BLOOD

SIR,—The article by Dr Dudley and his colleagues (Feb 8) is of great interest to those of us in the United States who have been concerned with the development of improved blood-transfusion equipment The studies reported undoubtedly represent a sincere effort to compare plastic and glass containers, and at first glance the conclusion that red cells are no better preserved in plastic than in glass seems to be supported by the experimental data

I feel it my duty, however, to point out that the experiments reported did not truly compare the preservation, during refrigerated storage, of red cells collected in plastic bags and glass bottles

The solution used in the bottles (A C D formula A, *U S P*) was transferred from the plastic bags to the bottles, presumably shortly before collection of blood This solution was autoclaved in the plastic bags and had been exposed to the plastic up to the time of use It was not autoclaved or stored in the bottles in which the blood was collected Thus the survival experiments of the bloods collected in the bottles cannot reflect deleterious effects on red cells of changes taking place in the solution on long exposure to glass There is increasing evidence that an interaction between contained solutions and glass surfaces does take place under such conditions

On Oct 12, 1957, a conference on the Deterioration of Parenteral Solutions was called by the National Research Council in Washington, D C At that conference a report on particulate matter in intravenous fluids was presented from the Walter Reed Army Institute of Research Using an instrument primarily designed for red-cell counting, it was found that solutions of saline, dextrose, and dextrose plus saline, dextran, and A C D , which had been stored for varying periods of time, registered particle-counts up to a million per 100 ml These particles were found to be silica Precipitation of fibrin from whole blood by means of finely divided glass is often used Such a reaction may well account for the frequent finding of "sludging" of red cells in blood collected in bottles This is destructive to red cells of stored blood, as shown by the elevation of the hæmoglobin content of plasma

In contrast, the A C D solutions processed in plastic bags had particle counts of less than 10,000 per 100 ml Widespread experience has shown hæmoglobin levels of plasma of blood collected in plastic bags to be consistently lower than that of blood collected in glass

It may therefore be truthfully said that the experiments reported merely demonstrate the excellent stability of A C D solution autoclaved and stored in plastic containers

No claim has ever been made that A C D blood collected in plastic bags could be used routinely beyond the 21-day limit prescribed by the Minimum Requirements for Human Blood (Citrated)[1] of the National Institutes of Health In the article by Walter[2] referred to by Dudley et al in eleven experiments the post-infusion survival of the red cells of blood stored 21 days at 4°C ranged from 66 to 93%, averaging 84%, certainly a very safe and satisfactory level, even for multiple transfusions

---

[1] Federal Register Department of Health Education and Welfare, Public Health Service (42 CFR, part 73, 1) Biologic Products, Whole Blood (Human) p 6540

[2] Walter, C W , Button, L N., Ritts, R E., Jr *Surg Gynec Obstet* 1957, 105, 315

Strumia[3] reported red-cell survival by the ^{51}Cr method of blood collected in A C D in bottles and in plastic bags, and stored for 21 days at 4°C This series comprised 9 glass bottles and 31 plastic bags obtained from four American manufacturers The mean values for bloods in plastic ranged from 62 to 87%, averaging 78%, whereas the average value in glass was 70% Dudley et al , referring to Strumia's article, state " these results were obtained from two autotransfusions and one transfusion with a compatible recipient "

The rate of deterioration of red cells of A C D blood is not a linear function of storage time, but becomes increasingly accelerated after about 2 weeks of storage, so that the red cells are unfit for use after 25–28 days after collection[4] No comparative values at a 21-day storage period were reported by Dudley et al The finding of no improvement of preservation of red cells in plastic over glass at a period when A C D blood is intrinsically useless, and may well be dangerous, is not very helpful for the clinician

Except for its importance to the military, a "dating period" in excess of 21 days is of no great significance in modern blood-transfusion practice It is our experience that blood is usually scarce and turnover rapid, so that a large proportion of bloods are issued within 10 days of collection This is very fortunate for the patient Consideration of factors other than red-cell viability are far more important in the safe and efficient conduct of blood-transfusion

Adherence to aseptic techniques in collection, processing, and administration is of prime importance

All rigid containers with rubber closures require puncture While the risk of contamination incident to collection (by trained personnel) is undoubtedly small, once the protective covering of the stopper has been pierced, that area is potentially contaminated Braude[5] showed that re-entry by puncture of the stopper carries a real risk of introducing microorganisms into the container All refrigerators are contaminated areas Pittman,[6] in reviewing fatal reactions resulting from administration of contaminated blood, found the gram-negative psychrophiles to be the most common causative organisms

This danger is so well recognised by the National Institutes of Health[1] that sampling by piercing the stopper, except for administration of blood, is forbidden Dudley et al 's remarks, " particularly those who object to opening bottles for samples ", suggests a truly alarming state of affairs

In the fabrication of the type of bag investigated, the donor tube with attached shielded needle is attached to the bag, and the assembly, with its contained solution, is autoclaved as a unit This reduces the risk during collection to the minimum of piercing the skin for phlebotomy The outlet ports are protected by sealed plastic tabs until the moment of assembly with the giving set, thereby eliminating direct contamination during refrigeration The risk of airborne contamination is also reduced, since the donor tube is filled with solution to the needle tip, and with proper technique no air can enter the tube before phlebotomy

Unfortunately, we have no record in this country of the rate of contaminations of bloods, or of the prevalence of pyrogenic reactions, since there is no requirement that reactions be reported Reaction rates with bottle-collected blood are estimated at 2–5% 6669 bloods were transfused from plastic bags in 1951–55, and of these 5525 were cultured The percentage of positive cultures was 0 53, and the percentage of pyrogenic reactions following infusion 0 83[2]—this is evidence of the superiority of the plastic bag over glass bottles in point of safety

The integral donor tube remains with the bag, and when serially numbered provides positive identification of blood and pilot sample at all times *Isolation of segments by dielectric sealing provides for* multiple sampling without entry of the container, and hence repeated cross-matching can be done with no risk of contamination of the residual blood In like manner samples for culture[7] can be obtained with complete safety at any period of storage

Dudley et al state " its routine use would confer minor advantages such as freedom from the danger of air embolus " Schmidt[8] has recently published case-histories of donors who suffered air emboli during collection of blood in gravity bottles Accidental occlusion of the air-vent permitted pressure to build up within the bottle so that air was forced into the donor's vein on release of the tourniquet Air embolism is a definite possibility when air is introduced into a bottle to speed administration, and this type of accident is commoner than is generally conceded Neither type of accident can occur with plastic bags since they require no venting, for taking or giving, and administration is hastened by external pressure

The plastic bag tested was designed not as a substitute for the glass bottle, but to free the practitioner from the limitations in the administration of *all* clinically useful components of blood imposed by rigid containers The vacuum or gravity (venous occlusion) bottles currently used in the United States were designed to meet the emergency of establishing an overseas whole-blood programme during World War II, and performed yeoman service They were intended only for the collection, transport, storage, and administration of whole blood, and not for subdivision into components

No successful widespread programme has ever been established for salvaging of red cells for clinical use from whole blood collected in glass bottles During World War II, the Korean action, and subsequently, all of the red cells of blood collected primarily for plasma have been discarded, and this has been the fate of over 15,000,000 units of blood collected in the United States

It has been known since 1947[4] that the survival of red cells of A C D blood from which the plasma has been removed within 24 hours after collection is at least equal, after 21 days of storage, to that of red cells stored as whole blood for a similar period This finding has recently been confirmed by the ^{51}Cr method on blood collected in plastic bags[9] *With suitable transfer bags, supernatant plasma can be* expressed from the collection bag and the residual cells can be usefully used for the full 21-day dating period

The indications for the use of separated red cells are now firmly established[10] *In current practice* about 30% of transfusions at the Peter Bent Brigham Hospital are of separated red cells All patients needing transfusions for the maintenance of a chronically depleted red-cell mass, or in whom the administration of whole blood involves the danger of circulatory overloading, receive separated red cells

Since most platelets are contained in the expressed plasma, and since, by proper manipulation, the buffy coat of centrifuged blood may also be discarded, sensitisation by platelets[11] and leucocytes[12] can be *minimised* *This is of* extreme importance to the patient needing repeated restoration of red-cell volume

The plasma harvested in the separation of red cells expands the donor panel Storage of plasma at room temperature for 6 months virtually eliminates the transmission of virus of homologous serum jaundice[13,14] Since this plasma can be pooled, it becomes available for emergency use without typing

The treatment of thrombocytopenia with infusions of platelet-bearing plasma or concentrated platelets is *now fully* established The percentage of platelets found to be viable (remaining in the circulation for from 2 to 5 days), when prepared in several types of equipment, was as follows[15]

Siliconed syringes, direct transfusion 80–90%
Fresh (1 hour) blood in plastic in A C.D or sodium edetate 75–80%
Platelet-rich plasma, plastic bag 60–65%
Platelet concentrate, plastic bag 50–55%
Fresh blood glass, gravity 15–20%
Stored blood (24 hours) glass 0

The flexibility of plastic equipment renders it most suitable for preparation of platelets for infusion

We feel that the incorporation of highly versatile plastic equipment into our practice of blood therapy has not only resulted in great economy in the use of blood but has often been life-saving in cases which would have been helpless to the physician with only conventional equipment

Finally, with regard to the minor technical difficulties mentioned, I believe it was Benjamin Franklin who said that " All arts are capable by practice of improvement "

MITRAL VALVOTOMY AND PREGNANCY

SIR,—My letter (April 5) may not have been expressed with sufficient clarity, but Dr Wade and his colleagues (April 19) have misinterpreted the comments on their paper

The problem of mitral valvotomy during pregnancy is discussed and then in the last paragraph it is stated that surgery during pregnancy is undesirable unless there is evidence for tight stenosis based on severity of symptoms before pregnancy began or objective evidence of long-standing pulmonary hypertension It is not stated that both these criteria should be present

Actually in our overall experience of patients proved to have tight stenosis electrocardiographic evidence of right ventricular hypertrophy by conventional standards in the conventional leads has only been present in 34% (although by slightly more liberal criteria and including the right-sided V leads in 65%)[1] The point at issue is this—if operation is advised solely on the basis of symptoms which first arose during pregnancy then, from our experience and that of others, there will be many cases in which the degree of stenosis found will be relatively mild and insufficient for the patient materially to benefit from valvotomy

In fact, Wade et al state in their paper that 4 of their 12 patients had only moderate stenosis which "could have been managed medically" Certainly pulmonary œdema may occur during pregnancy without tight stenosis, but in our experience such cases can always be managed medically and after the confinement undue dyspnœa on exertion disappears We do not agree with Dr O'Driscoll and Dr Drury (April 12) that operation should be deferred until after delivery because, as Wade et al point out, pulmonary œdema from tight stenosis may be fatal despite initial response to medical treatment

A NEW SULPHONAMIDE

SIR,—Dr Sklař (Feb 1) and Dr Platt (March 1) have written about their experiences with 'Sethadil' (sulphaethylthiadiazole), a sulphonamide recently introduced to this country This preparation was in use in a Naval hospital during the winter of 1957–58, and all cases of acute follicular tonsillitis were given a course for 3–5 days, hæmolytic streptococci were isolated from a single throat swab in fourteen out of forty-five cases and the average duration of sickness was 8 9 days (range 3 to 35 days), assessment of cure being clinical and not bacteriological Sethadil was well tolerated and there were no toxic effects

A review of cases admitted to the same hospital during the previous winter, 1956–57, revealed very similar results with other treatments During this period forty-six patients were under treatment and the form of therapy was dictated by the admitting medical officer, in this series hæmolytic streptococci were isolated in nineteen cases after a single throat swab The average duration of absence from duty of nine treated with aspirin gargles was 9 4 days, of eleven treated with aspirin gargles and dequalinium ('Dequadin') lozenges 9 5 days, of sixteen treated with parenteral penicillin 10 9 days, of six treated with parenteral penicillin and dequalinium lozenges 9 7 days, and of two treated with trisulphonamide tablets ('Sulphatriad') and dequalinium lozenges 8 days, in addition two patients treated with parenteral penicillin and then either streptomycin or aureomycin were sick for 8 and 10 days respectively The average period of sickness of all forty-six patients was therefore 9 0 days (range 3 to 21 days)

Parenteral penicillin has long been regarded as the treatment of choice in tonsillitis since its use is undoubtedly associated with a lessened risk of rheumatic fever and other complications, an advantage not obtained with sulphonamides However, where the risk of complication is negligible or there is a danger of penicillin sensitisation, a satisfactory response can be obtained with Sethadil

J M CLIFF

INTRATHECAL PHENOL FOR INTRACTABLE PAIN

SIR,—Following the excellent and comprehensive article by Dr Nathan and Dr Scott (Jan 11), Dr Allan Brown's comments (Jan 25) on intrathecal phenol for intractable pain are of considerable interest I agree that "until a sufficient period of observation has been completed it would seem to be prudent to restrict the intrathecal use of carbolic acid dissolved in myodil to the relief of pain of malignant disease"

I do wonder, however, whether he has been led to the same conclusion as myself about one of the underlying reasons for such uncertainty I pointed out[1] that, in late cases of carcinoma, the action of intrathecal phenol was delayed by areas of growth in roots and ganglia, and thus became ineffective In retrospect, I think this represented only half the truth, applying chiefly where the spine itself was involved In most cancer cases the neurones seem to have a variable and lesser resistance to phenol action Whether this is caused by preliminary inflammatory change and infiltration by round cells or inclusion bodies, I cannot say, but it makes some difference in the reaction following intrathecal phenol injections The impact is conversely more severe with non-malignant conditions, and the hazard is greater in the presence of scoliosis and arthritis or where the limb is already impaired from disease or previous operation

I have been making a further approach recently towards more accurate placing and dosage of phenol solutions for cancer cases, which may afford a helpful indication for safer injection in non-malignant conditions

First, pain areas are fully mapped out on standard diagrams of nerve segments[2 3] Five days after injection, these areas are remapped and further appropriate injections are made until pain is totally eradicated The segmental diagrams referred to are invaluable for this purpose, and I wish to acknowledge the help I have received from them

Secondly, an early indication of sensory effects is ensured by good backward rotation of the patient (as in fig 3B of my 1955 paper)[4] *For below* D12 *level, 1 ml of phenol (1 in 20 in* glycerin) is the arbitrary upper limit for safe dosage. Half this amount (i e., 0 5 ml) is injected, followed by immediate slight elevation of the patient for a second or two to move the solution on After a few moments, paræsthesiæ may begin, if they are severe or associated with cramps, for the second half of the injection less than 0 5 ml is given Skin sensation should be tested after the preliminary 0 5 ml If there is anæsthesia, the second part of the injection should be delayed until it has cleared and should be reduced below 0 5 ml

Differences in analgesia between the injected side and the opposite side give a valuable indication of where the agent is flowing and of whether further tilting is necessary in either direction

---

[1] Maher, R. M. *Lancet*, 1957, i, 16

[2] Brain, W R Diseases of the Nervous System, pp 30, 31 London, 1955

[3] Purves-Stewart, J, Worster-Drought, C. Diagnosis of Nervous Diseases, p 80 London 1952

[4] Maher, R. M *Lancet*, 1955, i, 18

The same technique, using two doses, each of 0 5 ml , is applied with the silver nitrate agent (1 ml of phenol 1 in 25, containing silver nitrate gr $^{1}/_{30}$ per ml) but this agent is never used for non-cancerous conditions, or above lumbar level Glycerin is used as the conveyor at the lumbar level since it does not tend to spread or to clog up roots for later injections

For *non-malignant* conditions, I have been recently using 0 5 ml of phenol, 1 in 20 in glycerin, at one session intrathecally At a later date, a similar injection of 0 5 ml can be given at another interspace if needed

Dr Lehoczky (March 8) again refers to the aqueous solution of phenol employed at the 1st or 2nd sacral foramen, which I always use instead of intrathecal injection for sciatic pain of non-malignant origin Since 1952 I have also used it frequently for sciatic pain of malignant disease, in one form or another Sometimes it is completely successful, but where it fails, the intrathecal method is more powerful Furthermore, transsacral methods cannot effectively reach higher segments for malignant disease It seems that each method has its own particular sphere of usefulness

The application of intrathecal methods is essentially for cancer, with a very limited and cautious approach for pain of non-malignant origin at the present time

Rochdale R M MAHER

NEW METHOD OF PHENOBARBITONE ADMINISTRATION

SIR,—May I briefly reply to Dr Penman (March 29) ?

1 " No conclusion whatever can be drawn from the data presented "—The facts are that each and all of the 18 patients showed a striking improvement, both in respect of personality and mental state, and also in the frequency and severity of their epileptic convulsions, whether or not they were receiving other drugs

2 " There can be no guarantee that the patients took their various anticonvulsants as regularly before the spansule period as they did during it "—For many years a rigid routine and discipline has been in force in this hospital whereby the epileptic patients are lined up regularly at the prescribed times of day, and the medication is administered in the presence of the nurse The same nurses had in fact been attending the 18 patients concerned for a number of years before the new method of treatment was adopted

3 " Much or all of the ' improvement in personality ' may have been due to added interest shown in the patients during this stimulating trial "—There had, prior to my " interest ", been no lack of stimulation in this respect, and on two occasions previously individual doctors, by their work with these particular cases, had in fact produced slight but temporary improvement both in the mental state and in the convulsions But they had not been able to achieve the definite and gradual reduction of convulsions, with final elimination, nor the striking improvement in the mental state and personality, which has resulted from the new method of therapy If such an " interest " is so important and valuable in the treatment of epilepsy, there should be a great future for psychotherapy in this condition, but few doctors who have had experience in the management of epileptics would agree that it is likely to have much success

4 " Since fits occur especially at times of bodily inactivity and mental vacuity, this added interest and stimulation may have helped to reduce their frequency "—Surely, the absence in the body (for approximately twelve hours, at night) of a sufficient supply of anticonvulsant medication is a more probable reason for convulsions The presence of an adequate supply of such medication throughout the twenty-four hours must give the maximum protection and help to the patient, as regards both disturbance of sleep and abnormal electrical activity within the nerve-cell Maintained control of both these important factors has been achieved since the introduction of ' Spansule ' therapy, in each and every one of the 18 epileptics treated Previously there had been many disturbances from fits and temper tantrums at night

5 " Credit for improvement cannot be assigned to any one of those drugs separately "—Much credit must be given to spansule phenobarbitone for the phenomenal improvements obtained in my patients after it was adopted If these improvements cannot be attributed to spansule, either wholly or in part, then they *must* be due to the drugs the patients were already receiving If these drugs, combined with " interest " and psychotherapy, were really so effective, many epileptics now in colonies and mental hospitals could have remained in society without danger to themselves or others

6 " Eighteen is too small a number of cases "—Dr Penman is, I am sure, aware that improvements such as I have reported can be proven to be significant and statistically valid with 18 patients or even fewer The advisability or otherwise of controlled trials, using inert substances, in patients with epileptic convulsions is open to discussion

7 " Dr O'Connor's results are striking indeed, but others hardly less striking have been overthrown by controlled trials, good examples being those of Kurtzke and Berlin and Booth et al "—Dr Penman's original contention that " *no conclusion whatever* " can be drawn, would seem to conflict somewhat with his closing remark, " Dr O'Connor's results are striking indeed " The fact that the trials to which he refers were both concerned with multiple sclerosis, and bore no relation to epilepsy with its specific complexities, makes his " good examples " appear weak and irrelevant

SEQUELÆ OF INTRA-ARTERIAL INJECTION OF THIOPENTONE

SIR,—We are interested in the sequelæ of inadvertent intra-arterial injection of thiopentone Gangrene has been reported after the use of 10%, and in a few cases of 5% solutions, but we can find no such complication reported after the 2 5% solution now in common use

We should be grateful if any of your readers could supply us with information, which will be naturally treated confidentially, of intra-arterial injection, or of cases where venous thrombosis occurred, when either 2 5% or 5% has been used

Radcliffe Infirmary, Oxford D L PRYER

PSYCHOSIS AND TREMOR DUE TO MECAMYLAMINE

SIR,—I was interested in the article by Dr Harington and Dr Kincaid-Smith (March 8), as I have had a similar case where mecamylamine was not given

A man, aged 60, had been known to have hypertension since May 18, 1955 He had had several attacks of congestive cardiac failure precipitated by an erratic consumption of digitalis He was admitted to the Addington Hospital on May 22, 1956, for an intercurrent *salmonella* infection He also complained of weakness, giddiness, and dyspnœa on effort His blood-pressure (B P) was 220/120 mm Hg There was no papillœdema, no renal dysfunction, and no anomaly of the central nervous system The heart was enlarged but there was no failure then The B P was controlled by reserpine 0 25 mg t d s and pentolinium 200 mg t d s He was discharged on May 23, 1956

Within a month the B P had risen again to 230/145, and the dosage of pentolinium was increased to 200 mg q i d After this the B P remained at levels varying from 160/105 to 180/120 for four months

On Sept 5, 1956, he complained of loss of weight and increasing depression On examination he was found to be heavily pigmented (more than his usual pronounced sunburn) and the mucosæ had a bluish tint There was a coarse tremor of all limbs, with a high muscle tone The reflexes were brisk, power normal, plantars flexor B P 180/100 Reserpine was discontinued because of the depression.

Two weeks later he was readmitted. The tremor was less obvious but the rigidity still present. His depression had deepened further and he was complaining of frequent involuntary seminal emission. The B.P. was 190/120. Lumbar puncture produced a normal fluid. The urine showed a trace of albumin and occasional red blood-cells. The blood-urea was 48 mg. per 100 ml.

Pentolinium was replaced by hexamethonium for two days, but then recommenced. The patient discharged himself after three days and had no more antihypertensive treatment.

A month later he was readmitted because of severe psychosis. He was disorientated and hallucinated, and showed paranoid tendencies. His speech was slurred but muscle tone was normal and the tremor very slight; B.P. 270/160. The urine contained a trace of albumin. The blood-urea was 27 mg. per 100 ml. The hospital psychiatrist diagnosed an organic type of psychosis due to cerebral arteriopathy associated with hypertension and suggested certification. The patient, however, absconded before this could be done and has not been seen since.

This case seems to be very similar to the cases mentioned by Dr Harington and Dr Kincaid-Smith, but this patient has at no time had treatment with mecamylamine. This would suggest that the symptom-complex may be due to hypertension per se or to its treatment with any ganglion-blocking agent.

Addington Hospital,
Durban
W. HIFT

INFANTILE GASTROENTERITIS

SIR,—Dr Librach has incurred much criticism for venturing to doubt if strains of *Escherichia coli* are of major importance in the ætiology of infantile gastroenteritis. During 1957 I admitted to hospital 38 cases of gastroenteritis in infants under two years. In all cases fæces were cultured, but *Esch. coli* of the presumed pathogenic types was isolated in only 3 instances. These included none of the 5 infants who were gravely ill. I have had similar experience in previous years.

Until the association can be more generally and constantly demonstrated, we should be permitted to keep an open mind on this matter. Incidentally, about ten years ago, proteus was frequently suggested as an important organism in this connection, a belief which now seems to be discarded.

Croydon
J. J. LINEHAN

PATIENTS FROM ABROAD

SIR,—I write as a practising surgeon in Beirut, Lebanon, who for 15 years has worked with a British surgeon specialist and has admired British medical skill and practice both at home and abroad.

Recently a colleague of mine heard that I was contemplating a voyage to England and asked my help in escorting one of his patients. This patient had been booked in a private nursing-home as a paying patient. Confirmation had been received that a bed would be available for the required period. On applying for a visa, we were informed that she could not be granted entry without permission from the United Kingdom. This, we were told, was to protect the British taxpayer. A reply-paid telegram was sent, but two weeks later we were still awaiting the answer.

If this patient is being admitted to a private nursing-home, and is therefore a paying patient, where is the risk to the British taxpayer or to the N.H.S.? If there were any danger of her being financially insecure, who would be more likely to know about it—the authorities in England, or the consular representative on the spot? Surely the foreigners seeking to benefit from British medical skill and progress and willing to pay for it should be encouraged to do so, and facilities should be given for their quick admission to the United Kingdom.

Beirut, Lebanon.
I. AYOUB

*** Dr Ayoub informs us that a visa was in fact granted for the entry of the patient into the United Kingdom, but arrangements had already been made for her to receive treatment in Switzerland, where she now is.—ED. L.

INTERMITTENT HYPERPARATHYROIDISM

SIR,—Dr Whitby (April 26) reports a case of hyperparathyroidism due to an adenoma which he claims was intermittently overactive; this claim carries considerable physiological implications. In fact, some of the findings are hard to reconcile with the idea of intermittent overactivity. Parathyroidectomy, which did not induce a hypoparathyroid state, halved the 24-hour output of calcium in the urine, whereas before operation no variations of similar extent occurred; the variations that did occur before operation seemed unconnected with changes of the serum-calcium level.

In proven cases of primary hyperparathyroidism, the serum-calcium level can be found to be within normal limits at times, and abnormal at other times, in one and the same patient; this emerges clearly from fig. 48 of Albright and Reifenstein,[1] and my own experience supports this.

A considerable experience of determining the 24-hour output of calcium in the urine of outpatients suffering from stone in the urinary tract has shown me that, when taking their customary diets, outputs of up to 350 mg. of calcium a day must be accounted as normal. This agrees with Pyrah's findings.[2]

Sheffield.
ARTHUR JORDAN

BUDGERIGARS AND POLIOMYELITIS

SIR,—This interesting correspondence raises some points on which I should like to comment, as the result of experience of avian diseases in the field and in the laboratory. It also clearly shows the need for closer cooperation between the medical and veterinary professions.

Leg weakness is a common symptom in ailing budgerigars, canaries, and other small birds, and if they are not handled and examined it can easily be confused with paralysis. In budgerigars the symptom is often associated with severe enteritis of unknown ætiology, which is very common in this species. Some specific diseases affecting cage birds also produce the symptom of leg weakness.

True paralysis, however, does occasionally occur in these species, and, apart from trauma, probably the commonest cause in budgerigars is the pressure exerted by renal neoplasms on one or both sciatic nerves, which in birds are in close contact with the kidneys.

It is also thought that certain vitamin deficiencies may cause paralysis in some species of cage birds.

Even if there is doubt that budgerigars may contract infectious poliomyelitis, it is well known that cage birds are occasionally infected with other diseases to which man is susceptible. The best example of course is psittacosis (ornithosis) which infects numerous species of birds and is commonest in this country in pigeons and recently imported psittacines such as parrots and parrakeets. A more common disease, however, is salmonellosis, usually caused by *Salmonella typhimurium*, which affects numerous species, including budgerigars and canaries.

Another disease (common in pigs and turkeys) affecting budgerigars and some species of finches is that caused by *Erysipelothrix rhusiopathiae*, which is transmissible to man, causing erysipeloid.

TESTING OF STERILISATION METHODS

SIR,—Dr Schwabacher, Dr Salsbury, and Dr Bailey (April 19) wisely advise against the use of the present "sterility test packets" They also affirm that Browne's steriliser control tubes are reliable This is certainly true if these tubes are correctly stored (at 70°F or less) Thus far Dr Schwabacher and her colleagues confirm conclusions reached by others[1-4]

It surprises me that they did not refer to Dr J C Kelsey's recent paper,[3] which clearly shows that unpredictable variables may complicate the testing of sterilisers with any organisms, but particularly with *Bacillus subtilis* and similar mesophilic spore-bearers The modifications of current procedure proposed by Dr Schwabacher and her colleagues seem to me only to add new complications Having read Dr Kelsey's paper and having had some experience of testing sterilisers with both mesophils and thermophils, I agree with him that organisms should be used to test sterilisers only for special purposes, and that for routine tests a chemical indicator is the most useful

Bacteriology Department,
Western Infirmary, Glasgow, W 1

J W HOWIE

RECORDS OF IMMUNISATION

SIR,—With the increasing amount of prophylactic immunisation, is it not time that something be done on a national basis to issue permanent records to all those receiving these injections? At present any person may have been actively immunised against any or all of at least five diseases (smallpox, diphtheria, tetanus, pertussis, and poliomyelitis) International vaccination certificates are already in force against smallpox, yellow fever, and cholera

It is rare for patients or their relatives, attending hospital casualty or other departments, to have the remotest idea whether or not they have been immunised against, say, tetanus, certainly they can never remember when it was done, and moreover they cannot be expected to appreciate the significance of the date of the test boosting injection

Parish[5] writes

> "Accurate record-keeping is essential, and should include the dates of inoculation, the correct name of the preparations, the batch numbers, the dosage administered, and reactions (local, general, etc) Every child should have a personal immunisation card which should be made out at birth and filed with the utmost care It must be readily available when inoculations of all types are given, or when the child contracts an infectious disease Intelligent parents could surely be trusted to safeguard duplicate cards, while the local authority remains responsible for the original The free movement of populations which takes place in modern times makes duplication of these records essential"

There are clearly many problems (records will be lost, and so on), but surely they are not insuperable

In many ways it is a pity that the wartime identity cards were abandoned they could have been modified to include information about blood-group and immunisations As far as immunisations are concerned a system of coloured inserts (each denoting a different course of injections), as used by the National Blood Transfusion Service for blood-donors, would go some of the way towards overcoming the problem of lost records Most people can remember the colour of their blood-group card even if they have lost it

It has been suggested that tattooing could be used for permanent recording, but the multiplicity of information required makes this impracticable, and neither children nor parents could be expected to agree to the procedure

Perry and Parish[6] suggested the use of a consistent set of abbreviated titles for all immunising substances, to ensure speedy, accurate, and unambiguous recording The first part of the abbreviation is the shortened name of the disease, if only one disease is named in the title, the abbreviation is three-lettered, (e g , Dip=diphtheria, Tet=tetanus), the only exception is that typhoid and typhus should be written *in full* to avoid confusion When protection is to be conferred against more than one disease, the abbreviations for their names are the initial letters—e g , TABT=typhoid, paratyphoid A and B, and tetanus

The second part of the abbreviation, which is separated from the first part by an oblique stroke, is either Vac (indicating any substance for *active* immunisation) or Ser (any form of serum for *passive* immunisation) There is again one exception, since both a toxoid and a vaccine are used for active immunisation against the staphylococcus, Tox is used for toxoid

The possibility of international adoption explains the preference for "Vac" instead of "Pro"

When necessary, the particular type of product may be specified in a third part of the abbreviation, again separated by an oblique stroke—e g , Dip/Vac/APT for diphtheria, alum precipitated toxoid

In this hospital, we are now actively immunising those who have had a general reaction to a test dose of tetanus antitoxin, and shortly intend to offer a course of toxoid to anybody that has had this antitoxin, so the problem of these records is considerable If there is enough support from others even more concerned than we who are working in hospitals, surely the Ministry of Health could be persuaded to take action on this very important problem

Orpington, Kent

KEITH J RANDALL

FREQUENCY OF THE TRUE (CHROMATIN-POSITIVE) KLINEFELTER'S SYNDROME

SIR,—The frequency of the true or chromatin-positive Klinefelter's syndrome has been estimated as 1 in 10,000 males[7] Our findings suggest a frequency as high as 1 in 1000

As the syndrome is probably often associated with mild mental deficiency,[8, 9] we examined the chromosomal sex by buccal smears of every second boy of the 671, aged 7 to 15 years, who attend the special State school for children with mild mental deficiency (I Q is in general between 75 and 85) in Zürich Of the 336 boys examined, 8 have been found to be chromatin-positive An independent observer (Prof H R Wiedemann in Krefeld, Germany) studied the blood-smears of these 8 boys and confirmed our results 6 of these boys are aged 12 years or younger and 2 are 13 or older All have normal male external genitalia The younger 6 show no signs of puberty and no gynæcomastia The older 2 have pubic hair, gynæcomastia, very small testes in view of their puberal development, and increased gonadotrophin excretion In the younger 6 no hormone studies were done Testicular biopsy was done in only 1 of the younger boys, it showed no tubular sclerosis and absence of Leydig cells, which is normal at this age[10] A detailed report about all 8 boys will be published later According to common views these boys must all be regarded as

examples of true (chromatin-positive) Klinefelter's syndrome (with a remote possibility of true hermaphroditism)

As we found 8 cases in half of the 671 boys with mild mental deficiency, the estimated number with Klinefelter's syndrome in the whole group is 16 The number of boys of the same age-group in the same city is 19,965 This means that the frequency of true Klinefelter's syndrome among boys with mild mental deficiency is 1 in 42, and among all boys at least 1 in 1248 As we know several other patients with Klinefelter's syndrome in the same city, who were intelligent enough to pass the normal school, the frequency among all males must in fact be higher, probably about 1 in 1000

NEOPLASIA

SIR,—May I, as a speaker on endogenous cancer at the conference on Neoplasia, reported in your issue of April 19, emend some impressions which it was not my intention to convey?

Discussion of old theories of cancer—for example, that senescence *might* be a cause—does not imply agreement Cells of young children are liable to malignant change as we know from the occurrence of embryomas, and fœtal cells grafted together with carcinogenic chemicals readily become cancerous

Although it is possible to induce cancer by subcutaneous or topical application of various chemical compounds, some even of endogenous origin, this does not exclude the possibility that the vast number of sporadic tumours are *not* caused by similar conditions in nature Inbred strains of animals, in which spontaneous tumour incidence is often greatly increased, provide material for testing other ideas But I would not myself postulate anything as vague as a cell "irritant"

Royal Beatson Memorial Hospital,
Glasgow

B D PULLINGER

TOXÆMIA OF PREGNANCY

SIR,—The continuing attempts to incriminate aldosterone in the ætiology of pre-eclampsia, in view of all the evidence denying it a share, merely reveals hypothetical ingenuity without plausibility

Unless it can be shown that salt restriction in the diet *enhances* the toxæmic process the following data further deny aldosterone a part in the production of pre-eclampsia

Orti et al [1] have proved the presence of an aldosterone-stimulating substance in the urine of adrenalectomised rats deprived of salt, by injecting their urine into intact hydrated rats in which it caused a *decreased* excretion of salt Quite obviously this substance in the urine of the adrenalectomised rats deprived of salt could not have been aldosterone, although it provoked the secretion of aldosterone when injected into the intact and hydrated subject

It seems therefore that depriving an animal of salt indirectly provokes aldosterone secretion All such deprivation would therefore conduce to salt retention and *if in significant amounts* to toxæmia—which is not a clinical experience This evidence further denies aldosterone ætiological significance

CLINICAL GERIATRICS

SIR,—The replies of Dr Agate and Dr Howell (April 5) to my query, arising from Dr Howell's original letter, as to what exactly constitutes "clinical instruction in geriatrics", are largely irrelevant.

Dr Agate's statement, "Elderly people with pneumonia *seldom exhibit any pyrexia*", is surely an exaggeration if the word "seldom" means what it usually does That delirium is fairly common in elderly patients with infections has been known for centuries, and has, surely, been taught in teaching hospitals for many years That infarction is frequently silent in people over 70 is possibly true, but the word "frequently" is surely hyperbole. Is occlusion "silent" more commonly in those in the seventies than in those in their sixties? Moreover, does such incidence refer to first attacks? These are very important points Dr Agate's description of geriatrics as "hard work in the clinical field" is an imaginative metaphor, but exactly what does it imply?

Dr Howell queries my citation of 68 for the age of my hypothetical patient To him, apparently, geriatrics starts at 80 Is there any official view as to what constitutes geriatrics? I should have thought that the age when a person is legally entitled to an old-age pension would be the only acceptable definition But, on the other hand, I remember an international conference on geriatrics held in London when several American physicians included *in their series of patients* some even below the age of 50 Is not all this classification of diseases according to age very artificial?

London, W 1

M H PAPPWORTH

ORGANISMS IN THE RESPIRATORY TRACT DURING ACUTE RESPIRATORY INFECTIONS

SIR,—The excellent contributions by Dr Brumfitt and his colleagues [1] and by Dr Steiner and his colleagues (March 22) prompt me to refer to the importance and value, from a diagnostic point of view, of the presence of specific antibodies in bronchial mucin

In 1918, I investigated the exudate of dysentery stools for agglutinating antibodies to the dysentery group of organisms,[2] and found that specific agglutinins were present in diagnostic amounts at an early stage of infection

Since then, investigations have been carried out by several workers (their findings have been summarised by Morgan et al [3]) on the presence of local antibodies in the mucus derived from the intestine and reproductive tract and from the bronchi [4-8]

If sputum, to which has been added a small volume of saline solution, is subjected to mechanical shaking with glass beads and centrifuged, the supernatant fluid can be investigated for its antibody agglutinin content against stock suspensions or against suspensions of selected colonies from plate cultures These tests are much facilitated by use of the Garrow agglutinometer slab method [9,10]

In this way bacterial flora of the mouth and pharynx (which do not produce antibodies) can be excluded and the necessity of obtaining material from bronchi by direct aspiration and swabbing becomes unnecessary

THE Y CHROMOSOME IN MAN

SIR,—In collaboration with Mr Peter Dickinson I have recently investigated a case which appears to illuminate the function of the Y chromosome in man

The details, briefly, are that, in the course of an operation for left inguinal hernia, a man was found to have, in the hernia, a uterus and uterine tubes and a right undescended testis The left testis was in the scrotum The penis and scrotum were quite normal No ovarian tissue was found The oral mucosa and neutrophil nuclear morphology were chromatin negative The histology of the left testis is exactly that of chromatin-positive cases of Klinefelter's syndrome as described by Ferguson Smith et al[1] and that of a chromatin-positive case of true hermaphroditism published by Armstrong et al[2] except for the absence of Barr's chromatin mass The right testis displays an identical picture as far as the seminiferous tubules are concerned, but the clumps of interstitial cells are atypical

The coincidence of an identical type of tubular atrophy and hyalinisation in chromatin-positive Klinefelter's syndrome and true hermaphroditism and in this chromatin-negative case suggests

(1) That the testicular changes in the two former are due not to the presence of two X chromosomes but to the absence of the Y chromosome The presence of the testis is another matter

(2) That our patient, who has not two X chromosomes, has probably no Y chromosome

(3) The presence of uterus and tubes, and perhaps the atypical interstitial cells in the right testis, in our case, indicates that Y contains a gene which is antagonistic to the X feminising genes and plays a part with autosomal masculinising genes in the normal X, XX switch mechanism

I postulate the existence of two genes on the Y chromosome (1) a gene necessary for normal development and maintenance of the seminiferous tubules of the testis (perhaps it is necessary for normal hormone production by the interstitial cells), and (2) a male determining gene

A full account of the case is being prepared for publication

I wish to thank Dr Bernard Lennox, of the Western Infirmary, Glasgow, who has seen sections of the testes, and Dr C N Armstrong, of the Royal Victoria Infirmary, Newcastle, who has been very helpful in hammering out the theoretical implications of the case

Parliament

Too Many Prisoners

Mr Butler's speech a year ago in the House of Commons raised high hopes for the reform of our prisons, the debate in the House of Lords on April 23 showed how seriously progress is being hindered by the alarming rise in the prison population In opening the debate Lord PAKENHAM pointed out that since Mr Butler spoke the number of prisoners had risen from 21,600 to 24,309 As a result overcrowding was worse, and whereas in 1957 only 2000 men (and that was 2000 too many) were sleeping three in a cell, the number today was 4389 Nor was immediate relief likely, for the increase in the Borstal population had forced the authorities to use the first new prison to be built this century as an extra Borstal institution In view of the acute shortage of accommodation it was lamentable to find that in the estimates for 1958–59 the provision for new buildings and alterations (as apart from repairs) was down by £16,000 Given such prison accommodation and the present wave of crime, he suggested that it was important to keep down the number of people in prison The Maintenance Order Bill would do something to reduce the number of civil prisoners and he would also like to see an increased use of adult probation, more treatment outside prison for sexual offenders, the development of attendance centres, and the extension of a parole system

Turning to the important and neglected question of research, he agreed that this was probably better conducted outside Government departments But if the Government did not largely pay for it there were no signs of anyone else doing so In 1957–58 £3000 was allocated to research, in the estimates for 1958–59 the figure was £11,000 which though better was still derisive Excellent officials in the Home Office were showing a good deal of initiative in promoting projects, but clearly it had all to be on a pretty small shoestring Without an institute of criminology research would remain uncoordinated

He was glad that recruitment to the prison service had improved, and the number of officers had risen from 3636 in 1957 to 4093 today But this improvement, too, had been partly nullified by the increase in the number of prisoners The hours of work in central prisons were 30–42 a week, but in local prisons the average was only about 25 Though some good things had been done Lord Pakenham feared that our prison services were still "last in the queue" of the social services, and if present trends continued, they would soon need a telescope to keep their colleagues in sight

Lord MANCROFT admitted candidly that the Home Office's plans had been sadly affected by the present financial stringency and by the substantial and unwelcome rise in the prison population The total population of our prisons and Borstals was 24,500 at the end of March this year—the highest figure yet recorded The high proportion of this increase among young men was especially alarming, the Borstal population had risen from 2600 in 1956 to 4000 These young offenders were the early arrivals of the post-war bulge in the birthrate If this level of crime was carried forward into the full effects of the bulge, the situation in a few years' time would be appalling, and we might well expect a Borstal population of over 5000 But he hoped that this phenomenon would pass with the generation born just before or in the early days of the war

He agreed that the problem could only be tackled by increasing accommodation and reducing the numbers of prisoners and some progress had been made

It was hoped to establish an experimental attendance centre for men of 17 to 21 years at Manchester this year A second junior detention centre had been opened for 65 boys and a Borstal for 50 girls The new security prison was expected to be ready in June, but he regretted that it must begin its career as a Borstal A second new prison should be completed in 1960, and the new psychiatric prison in 1961, a new central Borstal reception centre in 1960, a girls' security Borstal in 1960, and a boys' in 1961 To meet the immediate need a Ministry of Supply hostel had been acquired as an open prison for 480 men

Research was of course fundamental to any consideration of the causes or treatment of crime, and last year the Home Secretary had set up a research unit within the Home Office itself Increased support had also been given to projects at universities and other institutions

Lord Mancroft pointed out that one of the greatest obstacles to prison reform was the inheritance of a large number of unsuitable but solidly constructed prisons, and it would be unrealistic to make any plans on the assumption that they could be replaced by modern establishments in the near future Overcrowding had hindered the Commissioners' plans for modernisation and conversion as it was no longer possible to clear space to allow the work to proceed But some improvements, notably in sanitation, had been achieved

Central bath houses had been completed at 7 prisons and improvements would be undertaken this year at 3 more A pilot scheme for modernisation of sanitary accommodation in wings, workshops, and exercise yards at Wormwood Scrubs should be completed next year, a similar programme had been started at Dartmoor, and a programme for gradually modernising sanitary accommodation in all prisons would begin next year

Speaking in the debate Lord ASTOR suggested that the prisons were in much the same position as the hospitals They had a sensible wise direction at the top, a devoted but overworked staff, and obsolete overcrowded buildings It was expensive to keep a person either as a prisoner or a patient, and it was therefore important that only the right people should go to prison, as it was important that only the right people should go to hospital

Continuing his simile he said that prisons were like hospitals where the patients had been sent by doctors who had had no specialist training, who had not had the benefits of laboratory tests on the nature of the disease, who all too often never visited the hospitals, who merely prescribed the amount of medicine the patient was to receive with little expert knowledge of its chemical contents, and whose future had little to do with the percentage of patients successfully treated If we ran our hospitals on those lines what a chaos there would be

But that was what happened in our prisons Our judges, our magistrates, and our recorders had no real training in penology Was it not extraordinary that no Law Lord had taken part in this debate? Lord Astor thought that this abstention showed the extraordinary detachment of judges towards prisons With the work of Freud we had had a real break-through in the study of mental health—a new and exciting chapter in the knowledge of how the human mind worked, what made people go wrong, and how treatment was likely to affect them As a cockshy, Lord Astor threw out the suggestion that the education of barristers should be extended to include, at some period in their career, a study of psychology and penology and some form of practical work such as prison visiting or probation-officer work Greatly daring he went on to suggest " refresher courses " for magistrates and even judges

Supplies of Morphine for Port Medical Centres

On the adjournment on April 24 Mr JAMES CALLAGHAN drew attention to the fact that though 24 of our largest ports had medical centres, staffed with qualified nursing sisters, which handled about 230,000 accidents a year they were not allowed to keep supplies of morphine for use in emergencies The National Dock Board had applied to the Home Office in 1950 and in 1953 but had twice been refused permission. Mr Callaghan described a distressing accident in Cardiff docks in October when a man's leg was torn off his body Though three State-registered nurses were in attendance the man had to be brought ashore and travel in an ambulance over 3 miles of bumpy dock road to a hospital before he received an injection of morphine

Mr DAVID RENTON, joint under-secretary of State for the Home Department, said that it must not be overlooked that, though morphine did good by alleviating pain, it did harm by masking symptoms which might be important in diagnosis This was one reason why it had been generally accepted by the medical profession that wherever possible a doctor should be present when morphine was administered Another reason for caution was that this country was comparatively free from drug addiction, and the reason was the strictness and efficiency of our system of control That system was based on the general principle that nobody should be in possession of a dangerous drug unless authorised by the law Our dangerous drugs legislation gave effect to international conventions which this country had ratified and which required the exercise of stringent control over the supply, possession, and use of dangerous drugs Within the framework of the legislation, however, special arrangements had been made for the administration of morphine in particular cases Generally, these special arrangements related to circumstances where accidents happened and where it would be impracticable or unreasonable to insist on the presence of a doctor for the administration of the drug Thus special authority had been given to certain first-aid men in the mines and to mountain rescue parties Docks varied a good deal as to their proximity to the nearest town or hospital from which doctors could be summoned At the moment there was no evidence that the circumstances of docks in general justified a broad exception to the general principle, but he was arranging for the matter to be urgently considered, first in relation to Cardiff docks in particular In making these inquiries the Home Office would give the fullest weight to humanitarian considerations and the desire of all to minimise suffering

QUESTION TIME

Russian Vaccine for Multiple Sclerosis

Dr DONALD JOHNSON asked the Minister of Health, as representing the Lord President of the Council, whether he would consult the Medical Research Council with a view to obtaining a supply of the Russian vaccine for multiple sclerosis for the purpose of conducting, in this country, suitable tests of the efficacy of this vaccine —Mr DEREK WALKER-SMITH replied No final decision can be taken about the use of this vaccine until information about it is received from the Soviet Union. In the meantime, in view of the evidence available from laboratory investigations carried out in the United Kingdom and in America which throw doubt on both its safety and effectiveness, the Medical Research Council does not propose to undertake clinical trials of its possible value in the treatment of multiple sclerosis Dr JOHNSON May I ask whether the Minister recalls that he also said that he will allow imports of this vaccine through private sources, and that people who are extremely anxious to effect such imports—if the vaccine is any good—are desperately in need of further guidance on the subject?—Mr WALKER-SMITH The imports are on the individual guidance and responsibility of a practitioner recommending it. The tests on this subject will take a long time to carry out. Meanwhile, pending information from the Soviet Union, my hon friend may be interested, for example, to look at the conclusions of Professor Dick, published in the *British Medical Journal* earlier this year, and he will also be able, I hope, to study the conclusions of Dr Sabin of Cincinatti when they are published

Dr EDITH SUMMERSKILL In view of the fact that we have little information about the ætiology or the treatment of this disease, can the Minister tell the House why, because there has been little success on the part of those concerned with the two inquiries, the Medical Research Council should not examine this vaccine, even though it does take a long time?—Mr WALKER-SMITH There is no evidence that any adequately controlled clinical trial of the effectiveness of this vaccine has ever been undertaken anywhere In a disease of such protracted course over many years in which all patients show periods of remission which may be complete for several years, the design and execution of a therapeutic trial is exceedingly difficult. However carefully planned any such trial may be, I am advised that it cannot be expected to provide reliable results in less than five years, and perhaps we had better await the Soviet answer

Mrs BESSIE BRADDOCK In view of the fact that the Minister is prepared to allow the import of this vaccine privately, does he not think it would be advisable for some investigation to take place? If perchance through a private experiment a sufferer got great relief, it might cause a difficult situation if this vaccine could be obtained only through private sources — Mr WALKER-SMITH The position is that I would not stop the import of this vaccine if it were undertaken on the individual responsibility of a general practitioner who took responsibility for his own judgment. But in the generality, from what I know and have so far been able to ascertain about it, I could not recommend it, pending further investigation, particularly in view of the conclusions, not only of Professor Dick or Dr Sabin to whom I have referred, but also of Dr Broman of Gotenburg

Poliomyelitis Vaccine

In answer to questions about the supply of poliomyelitis vaccine Mr WALKER-SMITH said Batches of vaccine from the two British manufacturers which were distributed to local health authorities last week total over $^1/_2$ million doses, and a batch of Canadian Salk vaccine of $^{1}/_{2}$ million doses will be distributed within the next few days Over $8^{1}/_{2}$ million doses of vaccine will then have been distributed in Great Britain since the start of the scheme, $4^{1}/_{2}$ million of them since the beginning of this year Further vaccine should be distributed next month These supplies will enable local health authorities to make good progress with vaccinations

In addition to what is already in the pipeline, I am arranging for the purchase of a further quantity of American Salk vaccine in addition to the 7800 litres and replacements previously ordered from Canada and the U S A

Mr Barnett Janner Does the Minister recollect that many months ago he was asked why he was not purchasing adequate quantities of vaccine from North America? Is it not a fact that had he ordered the requisite quantity and made allowance for a breakdown, he would be in a position today to meet all the requirements, as America then had supplies and was able to supply him? Is the Minister also aware that much of the vaccine that has been produced in America has been sold in America, and that he has been scandalously negligent in not providing what is necessary for this country?—Mr Walker-Smith When the original imports of Salk vaccine were arranged the Government were acting under the advice of the Medical Research Council that the imports should be regarded as a temporary measure until adequate supplies of British vaccine became available There was no reason at that time to foresee the interruption of British supplies on the scale which has unfortunately happened, because they had been coming forward regularly for some time before that date The stocking of Salk vaccine at that stage would have been inappropriate because it was not possible to make an estimate of the acceptability of Salk vaccine at that stage, having regard to the right of rejection The hon Gentleman has left out of account in his suggestion the consideration that the potency of this vaccine is not permanent It is a perishable commodity

Dr Summerskill As the Minister knows, the number of people eligible for inoculation is 10 million, and 50% of them have registered That means that there will be 10 million inoculations to be given if they are all to have 2 inoculations Can he say whether before June—that is before the time when poliomyelitis rears its very ugly head in this country—the 5 million registered will have had 2 inoculations?—Mr Walker-Smith I hope that that may be the case, but, as I have already explained, there are many unpredictable factors in this matter and we have to take account of them

Mr M Edelman Does the Minister recall that last year the Pasteur Institute was willing to supply large quantities of Lepine vaccine but that he took no action whatsoever? Does he also recall that the Prime Minister wrote to me last summer saying that there would be discussions between the Ministry of Health and French health authorities in order to make this vaccine available? Will the Minister say finally whether he or his predecessor, either directly or indirectly, ever gave any undertaking to Glaxo or Burroughs Wellcome that he would give them priority over potential overseas suppliers of vaccine?—Mr Walker-Smith I am not aware of any such undertaking in regard to priority He may be thinking of the recommendations of the Medical Research Council that British vaccine should be regarded as our main, permanent source of supply and that Salk vaccine should be regarded as a temporary supply In regard to French and other sources of supply, there would be many technical considerations involved before they could be brought into use—considerations which do not arise in the same sense with Canadian and American sources of supply It seems better, therefore, to get our supplies from transatlantic sources

Mr G R Chetwynd asked the Minister what was the cost of the purchase of anti-poliomyelitis vaccine purchased to date, giving separate figures for imported and other supplies —Mr Walker-Smith replied The total cost of supplies of poliomyelitis vaccine distributed to date in Great Britain is approximately £$1^{3}/_{4}$ million, between a third and a quarter of this amount was paid for imported supplies Mr Chetwynd Can the Minister give an assurance that the availability of this vaccine, both from home supplies and overseas, has not been held up or delayed in any way by a shortage of dollars or lack of resources for development of production at home?—Mr Walker-Smith There is no particular difficulty in regard to money In the estimates for 1958-59 £2 million is included for this purpose and represents 10 million doses If it should be necessary to have more vaccine, I am sure the House will be sympathetic to the submission of a supplementary estimate for that purpose

Mr Chetwynd asked the Minister the nature of the tests used before imported anti-poliomyelitis vaccine is issued to local authorities, and how long they take —Mr Walker-Smith Salk vaccine is tested by the manufacturers for safety, potency, and sterility in the country of origin The United States Government arrange, in addition, for safety tests and for potency tests The potency tests are on monkeys and the safety tests on tissue cultures and on monkeys The tests carried out by the Medical Research Council in this country comprise safety, potency, and sterility tests, involving safety tests on monkeys and on tissue cultures, and potency tests on monkeys The Medical Research Council tests may take up to twelve weeks, but are often completed in ten or less Mr Chetwynd While recognising the absolute need for safety in this matter, is it necessary to have a duplication of these tests and is it necessary for them to take quite so long?—Mr Walker-Smith The question about the necessity for duplication of tests merits consideration in the circumstances It is a fact that the record of the American tests has been increasingly reassuring over recent periods

Protective Clothing and Purchase Tax

In response to almost twenty questions asking why purchase tax was being imposed on miners' protective helmets and footwear and what revenue it would raise, Mr J E S Simon, financial secretary to the Treasury, replied The estimated yield of the proposed 5% tax on these boots and helmets is of the order of £100,000 per annum But the revenue to be raised was not a significant factor My right hon Friend proposed this change as part of a rationalistion of the purchase tax, which also involved reductions of the tax on miners' caps from 10% to 5% and on miners' belts from 30% to 5%

Mr Thomas Williams If the object of this tax was not the revenue to be derived therefrom, what was the other purpose? Does that other purpose justify imposing any duty on protective clothing such as these shoes and caps?—Mr Simon Where there is an anomaly in a tax, it involves unfairness and discrimination between one citizen and another Protective clothing was already taxed Members have had an opportunity on many occasions of discussing whether all protective clothing should be exempt, and it has not been found possible to do this

Mr G O Sylvester Is the Financial Secretary aware that this taxation will cause deep resentment in the coalfields, especially in view of the figure that the tax will yield, which is nothing when compared to the amount of accident to life and limb which these commodities have prevented and which happened in the old days when the men wore ordinary clothing?—Mr Simon I sympathise very much with what the hon Gentleman says, but I hope it will be understood that the tax is part of a larger transaction which includes reductions in purchase tax on some of the articles used by miners

Mr William Stones Is the Financial Secretary aware that many people in the mining industry have spent much time in recent years trying to persuade and encourage men who work underground to discard their prejudices and their cloth caps and to wear safety helmets and boots? Is he further aware that the people to whom I refer are deeply concerned about the possibilities of this imposition of purchase tax being likely to interfere with their efforts to persuade men to wear protective equipment, particularly in view of the meagre amount likely to be saved?—Mr Simon I know of these efforts, and I should be very sorry if they were in any way affected, but I should remind the House that the tax on protective helmets will be under 6*d*

Obituary

FRANK HAMILTON LACEY

T D, M D Manc., F R C O G

Dr F H Lacey, honorary consulting gynæcologist to the Manchester United Hospitals, died at his home in Sussex on April 11

He was born in 1879, the son of Dr T S Lacey, who practised in Oldham and Manchester Frank Lacey studied medicine at the Victoria University, Manchester, qualifying in 1906 He was resident obstetrical surgeon at St Mary's Hospital from 1908 to 1912, and later he served as anæsthetist and registrar His association with St Mary's was interrupted by his service with the R A M C during the 1914–18 war, but on his return to Manchester he was appointed to the honorary staff, and he remained an active member until his retirement in 1946 He was also consultant gynæcologist to Crumpsall Hospital and gynæcologist to the Christie Hospital For many years he was clinical lecturer at the University of Manchester He was a foundation fellow of the Royal College of Obstetricians and Gynæcologists

R N writes of his old chief

Dr Lacey endeared himself to his patients because of his real care and concern for them and his unending patience to ensure their welfare To the hospital staff he was known as Pop Lacey His cheerfulness and kindness made him liked by all who worked with him He took a keen interest in the teaching of both medical students and midwives, and I am sure many remember him as a teacher, for his style was rather novel His lectures and tutorials were rather in the nature of a continuous viva interspaced with graphic illustrations, usually of situations both medical and social which the students might meet in later life He was a raconteur par excellence, and the situations were often highly humorous with solutions a little removed from medicine Outside our profession he had many interests and one of his favourite pastimes was the training and racing of greyhounds

Despite a severe illness shortly before he retired, he recovered a degree of good health which allowed him to fulfil his lifetime's ambition—to be a farmer Leaving Manchester he moved south, and "down on the farm" he enjoyed many years of active retirement as a very good farmer He was devoted to his family, and in his home life was extremely contented and happy You always left his house with a deep impression that it was a real home, and that may have been the secret of his happy and cheerful outlook, for though quick of temper he quickly forgave any mistakes we young residents might make

GEOFFREY WILLIAM RAKE

M B Lond

Dr Rake, research professor of microbiology in medicine in the University of Pennsylvania and scientific director of the international division of the Olin Mathieson Chemical Corporation, died on April 20 at Princeton at the age of 53 He studied medicine at Guy's Hospital, but he had spent almost all his professional career in the United States

He was born at Fordingbridge in Hampshire and went to King's School, Canterbury He qualified from Guy's in 1927, taking the M B Lond with honours the following year After three years working in the department of pathology of Johns Hopkins University under Prof W G MacCallum, he became in 1931 assistant in pathology and bacteriology at the Rockefeller Institute for Medical Research in New York, where he made a special study of meningococcal infection and immunity As a result of this work he was put in charge of the laboratory study of an outbreak of meningitis in a Government camp, and his work in this epidemic led to important results in identifying meningococcus carriers Later he extended his studies to cerebrospinal meningitis and the pathology of pneumonia In 1937 he was appointed head of the microbiology division of the Squibb Institute, and later he became director of the institute and of the Squibb medical division In these new appointments his investigations and interests extended to include the virus and rickettsial diseases and the use of antibiotics He travelled widely in the Far East studying new pharmaceutical preparations and surveying research facilities In 1953 he visited India at the invitation of the Government, and the following year he was a guest lecturer at Taiwan National University He was also director of a research project on anaplasmosis which was jointly sponsored by Mexico, the United States, the University of Pennsylvania, and E R Squibb and Sons de Mexico In 1955 with Dr Harvey Blank he published *Viral and Rickettsial Diseases of the Skin, Eye, and Mucous Membranes of Man* Two years ago he visited London and returned once more to his old medical school

Notes and News

IMPERIAL CANCER RESEARCH FUND

At the annual general meeting of the Fund on April 29, the annual report[1] was presented The council has decided to appoint a director, to be in charge of all the Fund's research activities, and Prof G F Marrian has accepted this appointment Permission was received in January to demolish nos 44–46, Lincoln's Inn Fields, to make way for new laboratories and offices, for which detailed plans are being prepared

Among much research reported is a clinicopathological study of prostatic cancer Three groups of patients are being compared those who die within three years, whatever the treatment, those treated with hormones and surviving five years or more, and those who survive over five years untreated It is thought that in the first group the effects of treatment may be non-specific, and due to relief of obstruction or of sepsis, while the survival in the other groups may be due to retardation of growth—by treatment in the second group and by some natural mechanism in the third group These ideas are being tested by clinicopathological observation of patients, including measurement of hormone excretion in the urine before and after treatment In more than two-thirds of a group of cases of cancer of breast and prostate, an association is thought to have been found between the clinical course during additive or ablative hormone therapy and the fluctuation in the amount of œstrogen excreted in the urine The absence of an association may be due to hormone-independence or to stimulation of tumour growth by hormones other than œstrogen[2] In many cases removal of the gonads, adrenals, and even pituitary did not completely eliminate hormone production, the biological significance of the small amounts remaining is not known

SOUTHPORT'S NEW MENTAL HOSPITAL

On April 15, Dr G E Godber, deputy chief medical officer of the Ministry of Health, inaugurated the first phase of Greaves Hall Mental Deficiency Hospital at Banks, near Southport The new hospital was, he said, a sign of our awakened sense of responsibility for the welfare of the mentally afflicted Its purpose was not to take people in and keep them for the rest of their lives but to restore as many as possible to life in the community

The new hospital, which is to cost £3 million and to house 1000 patients, stands on the main Preston-Southport road within easy access of Southport itself and of the industrial area of Merseyside Since 1939 Greaves Hall, from which the new hospital takes its name, has been used as a mental hospital, and at present it houses 170 patients The hall itself will later serve as the administrative offices of the new hospital The patients will be distributed among 20 villas which will be scattered over the 150-acre estate 4 villas have already been built and 2 are nearly full It is also intended to build 70 staff houses The tree-lined avenues, spinneys, coverts, and ornamental gardens of the estate are being preserved wherever possible

Work on the first phase of the development began in 1955, and besides the 4 villas for patients mentioned above has included a boiler-house, water tower, control point, nurses' home and 28 staff houses Work on the second phase is expected to begin in the autumn and will include another 8 villas, central kitchens, dining-rooms, laundry, workshops, garages, a school, recreation hall, gymnasium, and farm buildings The third and final phase will provide more villas for patients and a general hospital for the institution

MEMORIAL TO KATHLEEN FERRIER

At a ceremony at University College Hospital on April 24 Sir Henry Dale opened the Kathleen Ferrier extension of the radiotherapy department and unveiled a plaque of the famous singer by Mrs Mary Gillick The Kathleen Ferrier Memorial Fund had made possible the extension to this part of the hospital where she was treated, and in addition to contributing to the cost of building and equipment, the Fund also provided for certain technical staff The equipment in the new extension includes apparatus for studying the effect of oxygen in enhancing the action of radiotherapy for malignant disease

Sir Henry Dale and Sir Benjamin Ormerod both spoke of the warmth and vitality that had made Kathleen Ferrier so memorable a person, even apart from the beauty of her voice Sir Benjamin recalled particularly vividly two of her concerts, one at the Royal Festival Hall when she sang in *Das Lied von der Erde*, and another in Manchester when Sir John Barbirolli and Dr Bruno Walter shared the conducting of *Messiah* Mr Myles Formby referred to the distinguished work that had

been done in the radiotherapy department under the direction of Dr Gwen Hilton and which could now be expanded thanks to the efforts of those who had initiated and supported the Memorial Fund Among those present at the ceremony were Dame Myra Hess and Mr Hamish Hamilton

PHYSICIANS IN CONFERENCE

THE Conference on Anæmia and the Alimentary Tract, to be held by the Royal College of Physicians of London on July 25 and 26, is an interesting departure In devising this meeting, which, if it proves successful, may be the first of a series, the college has aimed not so much to engage in postgraduate training as to provide a means for the information of consultants, who will be able to exchange views informally, and the details of this first meeting, announced in our advertisement columns this week, make it clear that most of the speakers are themselves furthering knowledge of the subject.

A NEW CAUTIONARY CARD

WE have referred [1] to cards that are, or might be, carried by people with chronic illnesses to warn doctors about their condition in case of emergency, and we suggested that such cards might be used by those taking long courses of such drugs as cortisone, ganglion-blocking agents, and antibiotics The American Heart Association (44, East 23rd Street, New York 10) has produced a card, designed as a wallet insert, for people having long-term anticoagulant treatment. It specifies the drug that the bearer is having, and his blood-group, and gives advice on what to do in emergency illness or accidents

---

University of Oxford

It is proposed to confer the honorary degree of D SC on Dr Arne Tiselius, professor of biochemistry in the University of Uppsala

University of Edinburgh

Dr Alan Peters has been appointed lecturer in anatomy

University of Glasgow

On April 26 the degree of M.D was conferred on the following

William McNaught, A J O Hea and A A Robin (*with commendation*), Bernard Camber, Ella I McNaught

Dr M. G P Stoker, Huddersfield lecturer in special pathology in the University of Cambridge, has been appointed to the new chair of virology at Glasgow

Dr Stoker, who is 39 years of age, studied medicine at Cambridge and St Thomas's Hospital, qualifying in 1942 After holding a house-appointment at Lambeth Hospital he served with the R.A M C and took part in typhus research in India In 1947 he became assistant pathologist at Addenbrooke s Hospital, Cambridge He was appointed to his present lectureship in 1948 He is also director of medical studies and assistant tutor at Clare College He is a member of the World Health Organisation s expert advisory panel on zoonoses, and his published work includes papers on Q fever and other rickettsial and virus diseases

National University of Ireland

The following appointments have been made at University College, Dublin

Dr T B Counihan, professor of medicine, Dr D K. O Donovan, professor of medicine, Mr Eoin O'Malley, professor of surgery, Mr P A. FitzGerald, professor of surgery, Dr J W Harman, professor of pathology, Dr P J Cannon, professor of pharmacology, Dr Oliver FitzGerald, professor of therapeutics, Dr P N Meenan, professor of microbiology as applied to medicine

Louis Rapkine Lecture

This lecture will be given by Dr Jacques Monod of the Institut Pasteur, Paris, on Monday, June 2, at 5 15 P M, at the Institut Français du Royaume-Uni, Queensberry Place, London, S W 7 His subject will be the permeases—specific factors of cellular permeability

Royal College of Physicians of London

At a comitia on April 24, with Dr Robert Platt, the president, in the chair, the following were elected to the fellowship

PANDIPEDDI KUTUMBIAH, India, J O MERCER, New Zealand W F CONNELL, Canada J H WALTERS, London S S MISRA India F S BRIEN, Canada SAUL ADLER Jerusalem, THOMAS SIMPSON London WILLIAM GOLDIE Leeds W A OLIVER, Norwich E JOAN STOKES, London J E. CLARKE, Australia, M A RUGG-GUNN London C J C G HODSON London, J L PINNIGER, London, URSULA JAMES, London D DE LA C MACCARTHY, Aylesbury, Bucks J P M TIZARD, London MARTIN ROTH, Newcastle upon Tyne A T JONES, Liverpool, W S PEART London, H E DE WARDENER, London DAVID STAFFORD-CLARK, London A D CHARTERS, Kenya, P H DAVISON Birmingham S C GOLD London M D MILNE, London, E B ADAMS, South Africa I C K MACKENZIE London S W STANBURY, Hale Barns, Cheshire S T ANNING, Leeds, D H COLLINS, Sheffield, J S I SKOTTOWE Oxford C H GRAY London THOMAS MCKEOWN, Birmingham J S MITCHELL, Cambridge, SIR LINDOR BROWN, London, EDWARD FORD, Australia, SIR HANS KREBS, Oxford

The following having satisfied the censors' Board were elected to the membership.

B I Chazan M.B Glasg , Gordon Cohen M B Cantab , G L Donnelly, M.B Sydney, G H Fairley, B M Oxon., Nellie P Fernando, M B Ceylon, P N Francis, M.B. Sydney, Morris Greenberg M.B Lond C B Hatfield, M.D Alberta, T D R Hockaday, B.M Oxon , R D Hyde M B Cantab , J H Jones, M.B Cantab , G S McL Kellaway M B N Z , R S Kocen M.B Leeds, Albert Kusklick M B W'srand, P J Lachmann M B Cantab , Hermann Lehmann, M B Basle Emanuel Lewis M B. Queen's Institute of District Nursing

This institute will hold a conference at Church House, Westminster, S W 1, on Tuesday, May 6, at 2 30 P M , when Dr J A Gillet and Dr John Fenton will speak on ageing and the over-60's and schemes for the employment of elderly people

Institute of Child Health, London

On Tuesday, May 27, Dr G M Guest, of the Children's Hospital Research Foundation, Cincinnati, will give a lecture on studies of insensible weight loss, and on Tuesday, June 24, at 5 P M Prof J H P Jonxis, professor of pædiatrics at the State University, Groningen, will speak on diseases due to abnormal hæmoglobins The Simpson Smith lecture will be given on Wednesday, July 23, by Dr W J Potts, surgeon in chief of the Children's Memorial Hospital, Chicago His subject will be congenital atresia of the œsophagus All the lectures will be given at 5 P M at the Institute, The Hospital for Sick Children, Great Ormond Street, W C 1 Tickets for the Simpson Smith lecture may be had from the dean of the institute

Wellcome Trust

Among the grants totalling £108,630 sanctioned by the Wellcome Trustees for the half-year ended March 31, 1958, were the following

Institute of Cancer Research, University of London—£40,000 for the cost of including a Wellcome Laboratory of Pharmacology and Experimental Chemotherapy in the proposed extension of the Chester Beatty Research Institute

Government of Kenya—Up to £10,000 for the cost of adding a Wellcome Research Library to the Medical Research Laboratories at Nairobi

Nuffield Department of Surgery, University of Oxford—About £16,500 for the purchase of a Gibbon-Mayo heart-pump for use in research on the surgery of the heart

Department of Pharmacology, University of Sydney, New South Wales—About £3000 for a scintillation spectrometer for work with radioisotopes

Department of Pharmacology and Therapeutics, University of Manitoba, Winnipeg—£13,000 to provide the stipend of a Wellcome research fellow for six years

International Congress of Balneology

This congress will be held in Marienbad, Czechoslovakia, from Sept 8 to 13 Further particulars may be had from the secretary of the congress, Reznicka 5, Prague 2, Czechoslovakia

Institute of Hospital Administrators

The Institute is holding its annual conference in London, in conjunction with the International Hospital Equipment and Medical Services Exhibition, from May 5 to 7 at the Empire Hall, Olympia Further particulars may be had from the secretary of the Institute, 75, Portland Place, W 1

Electrophoresis in Clinical Biochemistry

The southern region of the Association of Clinical Biochemists and the Society for Analytical Chemistry will hold a joint meeting on this subject on Wednesday, May 7, at 7 P M at Burlington House, Piccadilly, London, W 1 The speakers will be Prof N H Martin, Dr W G Dangerfield, and Dr A L Latner

Rockefeller Foundation Grants

During the first quarter of 1958 the Foundation distributed $4,300,000 Grants for medical education and public health amounted to $910,000, and for biological and medical research $576,000 The grants include $33,500 to the Welsh Regional Hospital Board (over five years) to continue aid for research on the biochemistry of the nervous system under Dr Derek Richter at the Neuro-psychiatric Research Centre at Whitchurch Hospital

British Association of Physical Medicine

At the Association's annual dinner, held in London on April 25, Prof Robert Platt, F R C P , remarked that one of its objects was the achievement and maintenance of physical fitness He owned that his own idea of physical sport was a good hard game of chess health must not be confused with strength Continuing more seriously, he said that, with the growth of knowledge and techniques, specialisation was inevitable, but specialisation should not interfere with the relation of patient to doctor, *which belonged to the art of medicine* and not to any particular specialty Today medicine was more satisfying than ever before, because so much of science was at its command There used to be much humbug Now there was no need for pretence the profession could be frank about what it knew and what it did not know Professor Platt observed that if he had to found a new society (which, he added, heaven forbid) he would name it SAGIM—the Society for the Abolition of Gloom in Medicine The National Health Service had its faults, but it should not be blamed for everything Dr Philippe Bauwens, the president, responding to Professor Platt's toast of The Association, reported that this had had a good year Dr Hugh Burt spoke well of The Guests, and Dr Ian Grant, president of the College of General Practitioners, responded

---

Sir Oliver Franks has been appointed chairman of the board of governors of the United Oxford Hospitals

Prof Richard Ellis and *Dr Bernard Schlesinger* are visiting Turkey, under the auspices of the British Council, to attend the National Seminar on Child Health Problems

A meeting of the West Midlands Physicians Association will be held at Burton-on-Trent General Hospital on Saturday, May 31, at 11 A.M

The Society for Music Therapy and Remedial Music, which has been set up to promote the use of music in the treatment, training, and reablement of children and adults with emotional, physical, or mental handicaps, is holding its first meeting this Saturday, May 3, at 3 P M at Overseas House, Park Place, St James' Street, London, S W 1 Prof W A Robson is the chairman and the hon secretary is Miss Juliette Alvin (6, Westbourne Park Road, W 2)

A booklet, containing abstracts of papers submitted for the Benger prizes for original observations in general practice, has been published by Benger Laboratories, Ltd Copies (5*s*) may be had from the College of General Practitioners, 54, Sloane Street, London, S W 1, proceeds from the sale of the book will be passed to the college

The Lancet · Saturday 10 May 1958

MEASUREMENT IN MEDICINE

MAX HAMILTON
M D Lond , D P M
SENIOR RESEARCH FELLOW, DEPARTMENT OF PSYCHIATRY,
UNIVERSITY OF LEEDS

LITTLE more than a century after the birth of scientific medicine the present day is seeing the beginnings of a new revolution—the infiltration of the ideas and methods of modern experimental biology In all branches of medicine a drastic fundamental re-examination of even the longest-held cherished ideas and practices is pursuing its iconoclastic way, and many of these practices, when weighed in the balance, are found wanting

These new ideas and methods are to be seen most clearly in the field of research, where they take the form of an increasing insistence on the proper design of experiments and statistical analysis of results The clinical trials initiated by the Medical Research Council have given a lead in this field and set appropriately high standards The same trends are visible also in clinical medicine, where they have appeared most prominently as an increasing dissatisfaction with the basis of clinical judgment, the rediscovery of " observer error ", and a rather unsophisticated demand for the replacement of clinical observation and judgment by mechanical or " instrumental " methods Particular emphasis has been placed on " observer error " in the assessment of radiographs of the chest, but, of course, the problem is a general one A consideration of the fundamentals of this general problem should help in solving current difficulties

I intend to show here, by starting with an analysis of the fundamentals of measurement and error, that clinical judgment and observation do not merely form an inaccurate method of doing something which ought to be done better, but have a legitimate and irreplaceable function in medicine

Nature of Measurement

Measuring things is such a familiar activity that its nature appears to be self-evident Only philosophers worry about it

The simplest form of measurement is that in which a population is divided into two classes with and without a given attribute, each individual is, in effect, compared against a standard which has or has not the attribute In a sense each individual acts as a standard For example, we may classify persons in the street into those who are and those who are not wearing a raincoat The common numerical equivalent of such qualitative dichotomies is that of 0 and 1 The average for the group represents the probability of finding an individual with the attribute

A slightly less simple form of measurement is that in which the two classes differ on the basis of intensity of attribute All members of the population possess it, some more and some less For example, we may divide the population of men into those eligible and those not eligible for admission into the Police Force, in so far as they do, or do not, exceed a given height This division could be made by comparing each individual with a standard individual who is of the lowest eligible height In practice a ruler is used, being equivalent to the standard individual as regards the particular quality under consideration

Instead of two classes the population may be divided into three or more classes, and in that case several standards will be required The easiest way of supplying these standards is to use the members of the population as standards Each individual is then compared with the others and judged to be greater or less In this way the individuals can be ranked in a series in which the number of classes equals the number of individuals The number of classes can be reduced by bringing together adjacent individuals into one class, and can be finally reduced to the lowest subdivision of two classes This case reduces to the simpler procedure already described

The arrangement of members of a population in an order is not restricted to one quality A complex of qualities can be equally dealt with, as when it is decided that one patient is more ill or more in need of emergency treatment than another Individuals can be placed in order of rank as regards more than one quality, but then the order will not necessarily be the same If several qualities give rise to the same rank order, these qualities are probably not truly distinct and may perhaps represent different manifestations of the same essential or underlying quality This point, and the problem introduced by errors which interfere with the " true " ranking, will be considered below

The methods described so far enable us to make comparisons only within the population dealt with If we wish to compare one population with another, we must have some method of reproducing the standard This is not necessary where the individual members of one population can be compared with those of the other, but this is equivalent to saying that all the individuals can be assembled into one population The essential point emphasised here is that measurement in its simplest form does not necessarily imply a standard which is reproducible in different places and different times Such a reproducible standard is required only when comparison is between one population and another

The usual method of making the comparison which is the basis of measurement is to observe together the standard and the individual to be measured The comparison is " side by side " This is not always possible, and in medicine it is common for the standard to be not only absent but also impossible to obtain Thus, when we compare a patient's present state with what he was previously, it is impossible to make a direct comparison Comparison here is between the individual as observed and as he is remembered either by himself or by the physician This method of comparison against a remembered standard is extremely common, both inside and outside medicine For example, the possessor of " absolute pitch " can compare any note he hears with the notes of the scale which he remembers, and can identify its position exactly Length can be similarly measured One can judge a person's height with reasonable accuracy and in seaside resorts and fairs one can find people who earn a living by judging a person's weight in the same way

There are other reasons why a comparison by simultaneous observation is not made, the commonest one is that in which simultaneous observation is impracticable—e g , when two musicians are compared on the playing of the same piece of music Another reason is that the standard is so complex that it is impracticable to make it For example, the radiologist judges a radiograph of the chest to be normal or abnormal, and he does so by comparing it against a "standard radiograph" of a normal chest Since no two chests are alike, the standard is more or less a sort of "average" obtained over the course of years and present only in the radiologist's mind It must not be forgotten that a chest can be abnormal in many different ways The physician listening to heart sounds or palpating an abdomen is in a similar position to that of the radiologist

It is often assumed that measurement requires a second characteristic the individual measures should be additive The classical example of such additive measures are those of length and weight Thus 5 cm and 1 cm not only equal 6 cm but also equal 4 cm plus 2 cm, and 3 cm plus 3 cm The same applies to pounds and kilogrammes This additiveness is never completely true in all circumstances, and in most cases is rarely so Even in the obvious example, that of distance, it is untrue when the distances become large enough Thus a traveller who goes 10,000 miles away from his home and then a further 10,000 miles in the same direction is not 20,000 miles from home but 5000 miles from it If he goes another 5000 miles he will be at his home It might be said that this is so only because the earth is spherical, but, according to the theory of relativity, the same is true of the Universe as a whole, and the Universe, by definition, has nothing else outside it In fact, many of the measures in science are not additive Thus two specific gravities cannot be added together

Theory of Errors

It may be laid down as a general principle that all observations (and these include measurement) are subject to error For the present purpose errors may be subdivided into two groups those due to errors of measurement, and those due to sampling of population Errors of measurement may be subdivided into random errors and bias There are special problems associated with the type of measurement that consists of comparison against a remembered standard

Bias

Bias is produced by several factors, some of which are well known and can be dealt with, and others are less understood One of the most important is that the standard may shift for various reasons For example, if the observer examines a series of objects which change regularly in one direction (perhaps from normal to abnormal) by very small amounts, adaptation, which may be sensory (peripheral) or psychological (central), may shift his standard An important example of this is the anæsthetist's difficulty in observing the appearance of cyanosis when it develops slowly The reverse movement of the standard may be produced when extreme examples appear Thus, minor signs may be regarded as positive, until the observer sees several examples of major signs, after which he will tend to disregard minor ones The classical example of this is the examination for finger-clubbing in the chest clinic

All such processes are psychologically an assessment of differences, and the minimum of perceptible difference is determined by several factors One of them is the direction of approach, and, where it is necessary to eliminate this bias, it is usual for measurements to be made by approaching from both directions For example, the astronomer measuring the position of a star on a photographic plate makes repeated measurements in half of which he moves his microscope to the star from the left and in half from the right Such methods of increasing the accuracy of his measurements are particularly important because the image of a star produced by a telescope consists of a small disc surrounded by concentric circles The centre of the small disc cannot be accurately found because its edges are not clear, and the random distribution of silver grains in the emulsion makes its outline difficult to define

Attempts to eliminate bias in clinical medicine are not always made Thus the old method of estimating blood hæmoglobin of necessity introduced the bias of direction The concentration of hæmoglobin was determined by putting a fixed quantity of blood, saturated with carbon monoxide, into a standard tube and diluting it gradually until it matched the standard specimen The result obtained by diluting a concentrated solution will always tend to be different from that obtained by going in the reverse direction—i e, by adding successive minute quantities of blood to a fixed quantity of water until its colour matches the standard

Bias may even be useful sometimes The minimal perceptible difference will be increased by fatigue but diminished by expectation, hence an observer who is expecting a change will detect it sooner than one who is not When a clinician takes a patient's history, it may predispose him to take notice of slight signs which might otherwise be ignored It is partly for this reason that the clinician emphasises the importance of taking a good history first and using it as a guide to further investigations, as opposed to starting off with a series of routine tests

The traditional procedure for percussing the heart illustrates this very well In the first place the history indicates whether the heart is likely to be affected and its size or position altered The physician then palpates the chest to detect the apex-beat, and this sets one limit to the outline of the heart He then percusses the upper level of the liver, partly because it is usually in a fixed position and partly because the contrast between lung and liver is the maximum that can be obtained in the chest The physician has therefore, as it were, anchored his observations within certain limits and defined standards for the observation of small differences The results of percussion are usually reasonably good

Enthusiastic sceptics have made occasional attempts to determine the accuracy of percussion by asking clinicians to percuss one side of the heart without any of the usual preliminaries The results usually demonstrate that such percussion is practically useless One can sympathise with those clinicians who so good-naturedly allowed themselves to be placed in an unfavourable light, but one must still consider such so-called investigations as irrelevant

There is a story of one such "inquiry" in which the physicians were asked to outline the heart of a cadaver from which the heart had been removed from behind The story goes that they did not notice what had happened If the experiment were to have any value at all, it should have been done on one of two cadavers, and the physicians asked to compare the two and to account for the differences, if any This would have demonstrated what every clinician already knows, that percussion is appropriately informative in the right circumstances

Bias cannot be eliminated by subjective attempts to correct it, because this may produce bias in the reverse direction or, as it is usually called, "leaning over backwards" It can be reduced by methods of measurement which diminish the range for the play of subjective judgment, but they cannot eliminate it For example, mobility and range of movement in a joint can be estimated by an observer, but the use of a protractor will tend to make the measurement more accurate Even then movements of the joint can be increased or diminished by enthusiasm or lack of it on the part of the patient and his physician, because often the limitation to movement is due to pain, which is extremely sensitive to emotional state For this reason it is now well recognised that, in clinical trials, the treatment should be given as a "double blind"—i e, neither the patient nor the physician knows which of two different treatments the patient has been given The method fails when the treatments give such very different results that they can be detected easily, but in that case such precautions are unnecessary On the other hand, serious difficulties arise when the results of the two treatments do not differ greatly, but they can be identified by the different side-effects To deal with this requires not an understanding of statistics or experimental design but an intimate acquaintance with the clinical phenomena under investigation and the problems of dealing with them

The shifting of the standard in the course of a series of observations can be corrected by designing an artificial reproducible standard and by comparing each observation with it This is the method used by H G Wolff and his collaborators for measuring the degree of injection of gastric and colonic mucosa

If anæsthetists thought it necessary to notice the appearance of cyanosis at the earliest possible moment they could do so by devising a gadget consisting of a red background, the colour of oxyhæmoglobin, which could be covered by one or more layers of opalescent material to simulate the skin, and by a buff transparent sheet to imitation pigmentation In this way the anæsthetist could make a match for the appearance of the patient's ear and cheek before operation, and use it during the operation to detect the first appearance of cyanosis

Temporary shifts of the standard due to the nature of the material examined can be reduced by dealing with small batches at a time and starting off by two standard specimens—e g, radiographs, one of approved normal and the other abnormal Failing such standards, it is a great help to make careful accurate detailed definitions of normal and abnormal, and to read them through before starting each batch

Random Errors

Since bias is, by definition, those sources of error which tend to alter measurement in one particular direction, all other sources of error are random errors, and the theory of errors is concerned largely with them In its simplest form it deals with the large number of possible causes which will tend to disturb a given measurement by a small amount (Large disturbances must be eliminated in the experimental design) These small sources of disturbance are independent (because if they are not they become one source in effect) and tend to increase or to decrease a given measurement according to the direction whence they come or, alternatively, whether they are absent or present If they all act together in one direction, there will be a large error, if they act together in the opposite direction, a large opposite error will appear, and, if they act in opposite directions, the effects will tend to cancel each other out On these assumptions it can be shown that large errors will occur rarely and small errors frequently, and the distribution of these errors will be that commonly called gaussian or "normal"

If a graph be plotted of the frequency with which the different measurements occur it will be bell-shaped Since the errors tend to be in either direction, in the long run they will occur equally in both For this reason the simplest method of eliminating random error is to take many observations and to use their average (mean) as the "true" measurement An illustration will make this clear and show the underlying complexities in practice

A single measurement of a patient's blood-pressure is so liable to error that it is of little value in practice If it is important to obtain as accurate an estimate as possible, the measurement should be repeated several times and the mean calculated How often should the measurement be taken ? This can only be answered in a statistical sense, the greater the number of measurements from which the mean is derived, the more reliable is the mean, and its reliability can be described in a statistical sense This in itself may not be sufficient, for the observer himself may be liable to bias and random error The latter is part of the total random error and need not be further considered, but the observer's bias can be eliminated only by comparing his measurements with those of other observers If all observers were equally biased in one direction, the term true measurement—i e, measurement without observers' bias—ceases to have meaning, but, if they differ either in amount or direction or both, bias can be eliminated by using many observers and taking the mean of the observers Thus the best estimate of the patient's blood-pressure is the mean of measurements made repeatedly—e g, daily—by many observers, and its accuracy can be determined by the usual statistical methods

The customary way of recording such results is to place all the measurements made by one observer in a row, the measurements by another observer in a second row, and so on Thus each row represents the measurements made by one observer, and each column represents the measurements for a given day The mean of all the measurements may be regarded as being derived from the mean of observers or the means of successive measures The total variation (statisticians use the "variance") can be subdivided into that between days, between observers, and between observations, or residual This will indicate whether the errors due to observers is greater or not than that due to the measures, and in consequence will give estimates of observer bias (Technically this is the analysis of variance)

The use of arithmetical means gives equal weight to all observations It could well be argued that those measurements more remote from the mean should be given less weight than those nearer, and the same would apply to observers Thus the best estimate of the mean would be obtained by a weighted summation of the results If the observations are arranged in rows and columns as described, this is known as a matrix, and finding the set of weights is equivalent to finding the first principal component of the matrix or, in psychological terminology, a general factor

The precision of a measurement can be increased by a comparatively small number of repetitions to such an extent that, even when the original measurements were comparatively crude, the final result is remarkably accurate Thus, in an experiment by Keats, Beecher, and Mosteller, the analgesic effect of 10 mg of morphine given postoperatively were compared with that of an unknown analgesic by deciding whether each injection was effective or not The quantity of unknown analgesic equivalent to 10 mg of morphine, determined by this apparently crude technique, was found, and the unknown analgesic being also morphine, the equivalent was found to be 10 8 mg of morphine This experiment shows how accurately a quantity can be measured, even though each individual measurement is made by dichotomisation into effective or non-effective, high or low, absent or present

When the measurement is near or at the critical point at which the dichotomy occurs, it will be categorised as high or low 50% of the times equally As the measurement moves above the critical point, the proportion of "high" will increase towards 100% Conversely, as it moves downwards, it will be recorded as " low " for an increasing proportion of the time This is the method used in determining the lethal dose of a drug, which is defined as that dose which will cause death in 50% of the test animals It forms the basis of most methods of biological standardisation When such data are plotted as a graph they form an S-shaped (sigmoid) curve, which is derived from the gaussian curve by adding each frequency to the previous ones

An Experiment on Clinical Judgment

A simple experiment was devised to demonstrate this method applied to the detection of cyanosis A small rubber bag was fitted to a CO_2-absorbing canister, whose other end was fitted to a rubber anæsthetic mask The bag was filled with air, and a volunteer breathed and rebreathed this air through the canister As a result the oxygen in the contained air steadily diminished until finally the volunteer became cyanosed The time required for the first appearance of cyanosis was about $1^1/_2$ minutes The experiment was then repeated, and colour photographs were taken every 10 seconds The photographs were made up into colour slides, and the first (normal), last (just detectable cyanosis), and three intermediate ones taken for the experiment Several physicians were then asked to look at the slides one at a time, presented in random order, and to say whether they showed cyanosis or not The five slides were run through ten times for each physician Each slide was then given a score, being the number of times it had been rated as cyanosed Only five observers were required to place the slides in correct order The point of the experiment is that, when the last slide is compared with the first, it is only just detectably cyanosed, therefore the intermediate slides cannot be detected, because the cyanosis they show is below threshold

Assessment of Chest Radiographs

The overwhelming majority of the pictures obtained from mass chest-radiography are normal, a few are grossly abnormal, and some show minor changes It is these that form the subject matter of the controversies on observer error We may now consider a hypothetical experiment All the radiographs are placed in order running from the obviously normal to the obviously abnormal A radiologist examines them and rates them as normal until a point is reached when he begins to be doubtful He goes on until he reaches one that is obviously abnormal, and from then on, the rest are rated as abnormal This could happen only if error could be eliminated, which is impossible

However, there is a method by which error can be reduced to below any required minimum This consists of repeating the examination of the radiographs and rating them anew The original dichotomous rating will now be changed to three categories those pictures rated as normal twice, those rated normal and abnormal once each, and those rated abnormal twice Further repetitions of the procedure will eventually produce a series in which the pictures run from those found normal every time to those found abnormal every time By analogy with the little experiment on judging cyanosis, if the observations have been repeated often enough, this order will correspond to the true order (theoretically, will tend indefinitely in that direction)

Several difficulties render this experiment impracticable The first is that " abnormality " in a chest radiograph is not a simple matter All sorts of qualities in the radiograph can separately deviate from the normal, and, in so far as these are independent, the resulting ranking orders will differ according to which has been reckoned to be the most important The attitude of the radiographer may change at each viewing, hence he will not tend towards consistency Other radiographers may differ from him in what they regard as important To a limited extent these changes between different viewings and differences between different observers can be eliminated by careful discussion between them and, above all, by the formation of a collection of standard chest radiographs illustrating the different degrees of each type of abnormality The difficulty lies here in that the clinical significance of " abnormalities " seen in chest radiographs is not yet fully understood Much further work in following up these cases has yet to be done

The point to be emphasised is that discrepancies between repeated observations and between different observers is something to be expected It can be diminished by suitable methods—i e , by the provision of standard radiographs and by the appropriate training of radiologists—but it can never be eliminated The error produced by such discrepancies can be reduced to any level by sufficiently increasing the number of times each radiograph is observed and rated

At this point a new difficulty appears—an operational problem It is true that the number of cases of lung disease missed and the number falsely diagnosed as diseased can be diminished by increasing the number of times each radograph is examined, but a radiologist can only examine a limited number of pictures For every picture that is examined a second, third, &c , time, the picture of a second, third, &c , subject cannot be examined While the radiologist is ensuring that he does not miss any cases in one district, he is missing cases in other districts because he is not there examining them In practice the gain on the one hand is not completely counterbalanced by a loss on the other It is a long and troublesome job to collect people for mass radiography in a given district It is easy and quick to examine the radiographs a second and even a third time Of course, repeated examinations of radiographs need not necessarily hold up the activities of a mass radiography unit On the other hand, there are limits to the amount of work a radiologist can do merely in examining films He needs to be refreshed by the experience of examining films of chest disease, and even by examining patients, follow up work, and so on It should not be impossible, all these problems being taken into account, including the structure of a mass radiography unit, to work out a routine that would find the maximum of cases with the resources available But operational research has not yet penetrated very far into clinical medicine

Reduction of Errors of Measurement

The simplest and traditional method of reducing errors *of measurement* is that of instrumentation Fundamentally this consists of finding a device that will magnify the changes to be measured—e g , a long pointer So far as possible, observations made through the various senses are converted into visual observations—usually a change of length This is because the perception of small changes of length is more sensitive than any other Instrumentation eliminates bias and usually reduces error to a negligible order

Unfortunately it introduces new difficulties Radiography will detect very small amounts of cardiac enlargement or very slight thickenings of lung tissue, but this sensitivity immediately raises the question of the limits of the " normal " Examples of such problems are the size of the heart, basal metabolic rate, and blood-pressure

(Of course, this problem does not arise when the difference between the normal and the abnormal is very great—e.g., phenylketonuria and galactosæmia.) When small changes can be easily detected, the problem of interpretation becomes difficult.

Universal Unit for Clinical Tests

The practising clinician is faced with this problem in another way. The increasing number of biochemical and biophysical investigations (an increase which will continue for an indefinite period) means that the clinician has to burden his memory with an increasing number of standards. As a result it is customary for pathologists to indicate in their reports what is the accepted range of the normal. An even simpler way out of this difficulty would be that of determining the distribution of the measurements in healthy people, and then giving the measurement for the individual patient in terms of the standard deviation. The clinician would then know that any measurement differing from the normal average by two standard deviations would suggest a pathological deviation, and any measure more than three standard deviations would be almost certainly pathological. This would apply to any measurement—e.g., mean corpuscular volume, alkaline phosphatase, excretion of ketosteroids, and vital capacity. The introduction of such a uniform measure would be as beneficial to clinical medicine as the introduction of money was to a barter economy. An analogy to this is the introduction of the method of measuring electrolyte concentration by milliequivalents instead of milligrammes per 100 ml. This statistical unit is so simple that it would not be rash to prophesy that it will be almost universal before the century is out.

The theory of errors has been given in the customary form, in which each measurement is regarded as consisting of a part, the "true" measurement, and another part, the "error". Since the "true" measurement cannot be obtained by any known operation it is a mythical entity. Present-day philosophy of science discards such mythical entities and confines its attention only to those results obtained by clearly defined operations. All possible measurements—e.g., of blood-pressure—are then treated as a "group", of which any one is equally representative. A series of measurements is a sample from the group, and the mean, mode, standard deviation, &c., are regarded as properties of the group.

Sampling Errors

Sometimes we measure a group of individuals to determine the characteristics of the population, of which the group is regarded as a sample. Unless all the members of the population are exactly alike as regards the measurement (in which case only one individual need be measured), different samples will give different results. This situation arises when measurement is applied to the individual patient—e.g., when a sample of blood is taken for a cell-count. In a sense this applies to any function which varies—e.g., blood-pressure and hormone concentration. A series of measurements may then be regarded as a sample from all the possible measurements. What is required from the sample is an estimate of the characteristics of the population. The accuracy of this estimate depends on the size of the sample: the bigger the sample, the more accurate is the estimate. The only way to increase the accuracy (if the sample has been obtained in the best way) is by increasing its size. Instrumentation is of no help here, because this can only diminish the error of measurement. The size of the sample that is required depends on the variability within the population and the accuracy required. If the last two are given, the first can be calculated easily.

Measurement of Complex Functions

An excess or deficiency of a hormone gives rise to changes in many functions. What is the best way of measuring the excess or deficiency? Even when the blood concentration of the hormone can be measured this would not necessarily be informative, because different individuals show different concentrations under normal conditions, and it is very rare that the normal for the individual is known. Thus it is necessary to measure the changes in the functions concerned. The easiest method of dealing with this is to measure the most important function. Unfortunately in practice this often means measuring the function that is most easily or most accurately measured.

If only one function is to be measured, the best one to choose is that which differentiates most between the normal and abnormal, taking into account the accuracy of measurement. The one measure is then an "index" of the total functions of the hormone. This is not often satisfactory, and, when one considers, for example, the history of the study of disease of the thyroid gland, one single index can be very unsatisfactory. What is required is some method of combining the results of measuring different functions to utilise all the information available. The technique for this is known and had been applied to medical problems three times.

The problem is that of finding suitable weights for the individual variables. We may regard subjects with obvious hypo-, hyper-, and eu-thyroid function as distinct groups. The measures of a sample from these groups are taken, and the dispersion matrix of these variables is calculated. This is divided into the dispersion between groups and the dispersion within groups. The former is divided by the latter, and the largest principal component of the resulting matrix gives the best weights for maximal differentiation between the groups. This is the method of multiple discriminant functions of Rao.

It is sometimes possible to measure a complex function by an appropriate complex measure. For example, if it is desired to compare two treatments for parkinsonism, it could be done by measuring the improvement of the handwriting of the patients. The handwritings of each patient in a group of (say) 20 is first ranked from the best to the worst. The first, second, up to the tenth pairs are taken, and the members of each pair allotted randomly, by tossing a coin, to one or other treatments. The patients are then given the treatments, and at the end of the trial samples of their handwriting are again taken and ranked in order. The change in rank order of one group compared with the second group would measure the difference in the effects of the treatments. To determine the reliability of the ranking it would be necessary to have the ranking done by at least two independent judges. The average of the rankings of the judges would also be more reliable.

Measurement of Subjective States

Contrary to popular belief, this is simple in theory and difficult in practice. Theoretically, the subjective state of the patient is manifested by his behaviour, and all that is needed is to find some appropriate form of behaviour. This may range from the patient's own statements about himself, in current jargon his "verbalisations", to the way he deals with such complex problems as his relations to his family, friends, work, &c. This subject of psychometrics has been under investigation for over half a century, and the literature is enormous. The practical problem is to find a suitable type of behaviour and to utilise the most appropriate method of measuring it The example given above, ranking of handwriting, illustrates one common method

Another way of measuring subjective states is to measure concomitant physiological functions For example, the response to stress of the resistance of the palmar skin, due to sweating, can be used as a measure of anxiety, so also can the electroencephalographic sensitiveness to intravenous barbiturate This is a very indirect form of measurement and is better regarded as an "index" rather than a direct measure Indexes are very much used in medicine, thus the thymol-turbidity test is an index of liver function

The trouble with such index measures is that their applicability is very limited Thus measurement of skin resistance would be useless for assessing a tranquilliser that had some ganglion-blockading effect Its relevance in patients who have cerebral damage—e g, leucotomy—has not yet been determined

Conclusions

Clinical observation has been the foundation of medicine, both in research and practice It still is It is a method which is liable to error, but so are all observations, however made In recent years much attention has been paid to "observer error", whose presence has been mistakenly assumed to invalidate the method of clinical observation Observer error can be diminished to any required degree by suitable techniques, as can any source of error of measurement The value of clinical observation in research and in clinical medicine will increase, not diminish, as the methods of handling its limitations become more widely understood and utilised The day is far distant, if it will ever be reached, when readings from machines will supersede clinical observation

THE ORAL TREATMENT OF PERNICIOUS ANÆMIA

A NEW APPROACH

J G HEATHCOTE

BIOCHEMIST, DISTILLERS CO, BIOCHEMICALS LTD

F S MOONEY
M D, B Sc Manc
CONSULTANT PATHOLOGIST,
ST HELENS HOSPITAL, ST HELENS, LANCASHIRE

SINCE the early 19th century it has been appreciated that pernicious anæmia is associated with imperfect assimilation of food The early work was clearly confirmed by Minot and Murphy in 1926 when they demonstrated that liver given by mouth can cause remission of the disease

In 1929 Castle advanced his classical hypothesis that normal human gastric juice contains a factor ("intrinsic factor") which when given by mouth with a food factor ("extrinsic factor") found in meat, will restore the blood-picture in pernicious anæmia (see Castle 1953) Castle and Minot (1936) assumed that the two factors react together to produce the hæmatologically active principle, which is then stored in the liver and other tissues

When crystalline vitamin B_{12} became available it was tested orally and found to be relatively ineffective Ungley (1952), who summarised the results of several workers, concluded that in 21 cases of pernicious anæmia daily oral doses of 5 µg or 10 µg of crystalline vitamin B_{12} either had no detectable effect or produced a trivial response When given with normal gastric juice, however, vitamin B_{12} proved to be nearly as effective as when given by injection (Berk et al 1948) This led to the idea that extrinsic factor and vitamin B_{12} are one and the same thing (Castle 1953, Berk et al 1948) Nevertheless, even in the presence of normal amounts of intrinsic factor, the intestinal absorption of vitamin B_{12} was found to be surprisingly small (Glass et al 1954) Thus an increase in the oral dose of vitamin B_{12} from 0 5 µg to 50 µg leads only to an increase in hepatic accumulation from an estimated 0 45 µg to 1 5 µg Glass et al, therefore, postulated an intramural intestinal acceptor of vitamin B_{12}, and the non-absorption of increasing doses of vitamin B_{12} was attributed to saturation of this acceptor According to present concepts, therefore, the absorption of vitamin B_{12} by the human intestine is a complex process involving the presence of a facilitating substance (intrinsic factor) and possibly an intestinal acceptor substance as well

Castle's hypothesis has led to an enormous amount of work in the search for intrinsic factor

Extensive reviews have been written by Ungley (1952) and Grasbeck (1956), but few workers can agree even on limited properties for this elusive factor Castle himself (Castle et al 1930) concluded that the intrinsic factor "is certainly not pepsin", and this view was supported by the observations of Wilkinson (1930) Ternberg and Eakin (1949) showed that vitamin B_{12} combined *stoichiometrically with a non-dialysable* substance, apoerythein, in normal gastric juice The vitamin in this combination is not available to microorganisms that need it as a *growth factor, this microbiological* technique was therefore used to assay the vitamin-B_{12}-binding principle Eakin (cited by *Hall 1950*) found the concentration of apoerythein to be low in the gastric juice of pernicious-anæmia patients, and this led to the suggestion that apoerythein was identical with intrinsic factor However, the relationship of the binding principle and intrinsic factor is by no means clear (Wijmenga et al *1954*b, *Everse et al 1953*, Williams et al *1954*, Landboe Christensen and Hoff-Jørgensen 1955, Noer 1954, Gad Andresen 1954, Baker and Mollin 1955, Beerstecher and Altgelt 1951), and vitamin B_{12} can bind itself to many substances which have no intrinsic-factor activity (Gregory and Holdsworth 1953, Hall 1950, Wijmenga et al 1954a)

Nevertheless, since the glandular mucoprotein fraction of gastric juice was found to potentiate to some degree the effect of orally administered vitamin B_{12} (Glass et al 1951) the mucoprotein nature of intrinsic factor has become widely accepted The findings of Ternberg and Eakin (1949) and Glass et al (1951) suggest that intrinsic factor has a high molecular weight, and this has led to consistent attempts to prepare vitamin-B_{12} complexes containing a protein of high molecular weight with non-diffusible properties Available commercial preparations of intrinsic factor, however, are extremely variable in their effects, and some may even inhibit the absorption of vitamin B_{12} (Williams et al 1956)

There is a growing tendency to blame species specificity for the numerous failures of intrinsic-factor preparations (Wijmenga 1957, Schwartz et al 1957) Nevertheless as *The Lancet* (1957) has pointed out, the treatment of pernicious anæmia with relatively crude preparations of hog's stomach over many years has been entirely satisfactory (see Wilkinson 1949) This editorial suggested that the cause of the failure of commercial preparations may well lie in their mode of preparation However, it occurred to us that the fault might be even more fundamental, and that an entirely new approach to the problem of the ætiology of pernicious anæmia might be desirable

There are certain well-established experimental facts Firstly, we know that vitamin B_{12} is relatively ineffective by mouth, and that, alone, it cannot mature megaloblasts in vitro (Callender and Lajtha 1951) Thus the crystalline vitamin is not the active hæmopoietic principle per se Furthermore, Robinson et al (1954) have shown that, though most of the vitamin B_{12} in crude liver extracts is bound, it is not bound to protein as such, because the active vitamin can diffuse through 'Cellophane' This seems to indicate that, in the anti-pernicious-anæmia principle, the vitamin is bound to a molecule of fairly low weight—e g, a peptide Finally, almost all forms of vitamin B_{12} available as food are bound to proteins of high molecular weight and are thus non-diffusible through cellophane and non-assimilable by microorganisms This suggested to us that a simple proteolysis may take place in the stomach, in which the "bound" protein attached to the vitamin is degraded into a peptide In this "free" form it could then be simply absorbed by diffusion through the gut wall, and thence travel to the storehouse of the liver, to be released again into the blood-stream under the action of an enzyme, erythropoietin (Fried et al 1957) as required

On this new hypothesis the inconsistencies in the action of intrinsic-factor preparations can be accounted by variation in the molecular size of the bound protein components in such mixtures Thus it is not surprising to find that vitamin B_{12}, when bound to material of high molecular weight, even though the latter be comparatively pure, does not show any activity when given orally to patients with pernicious anæmia—e g, the sow's-milk-protein complex of Gregory and Holdsworth (1953) and the purified cobalamin-protein (fiog) of Wijmenga et al (1954a), which had molecular weights of 55,000 and 70,000 respectively

Good evidence for our hypothesis would be obtained if it could be shown that a peptide derived not from an animal intestinal (intrinsic) source but from a mould or bacterial (extrinsic) source promoted the oral absorption of vitamin B_{12} (as the complex) in pernicious-anæmia patients, and, in small doses, maintained such patients in health A brief outline is given below of the isolation and properties of such a vitamin-B_{12}-peptide complex which possessed none of the properties which previously have been claimed to be necessary for absorption of the vitamin by the human intestinal tract.

Properties of the Complex

The active vitamin-B_{12}-peptide complex (H P P /1) was derived initially from fermentation of a Streptomyces mutant under standard conditions The cobalamin-peptide was released from the protein complexes within the cells and concentrated and purified by a series of steps involving ion-exchange chromatography, counter-current solvent extraction, activated-carbon treatment and ammonium-sulphate precipitation A red precipitate was finally obtained which possessed the following properties

The vitamin-B_{12} portion of the complex was estimated spectrophotometrically at 550 mμ, at which wavelength the interference of the peptide portion is very small The ratio of peptide to vitamin B_{12} on a weight basis was 6 8 1 and, assuming a 1 1 molecular ratio of vitamin to peptide, the molecular weight of the complex would be about 10,000 The true figure was probably less than this in view of the fact that the complex was dialysable and ultrafiltrable through cellophane and collodion membranes The complex did not appear to dialyse, however, against ammonium-sulphate solution under conditions which enabled the uncombined vitamin to do so

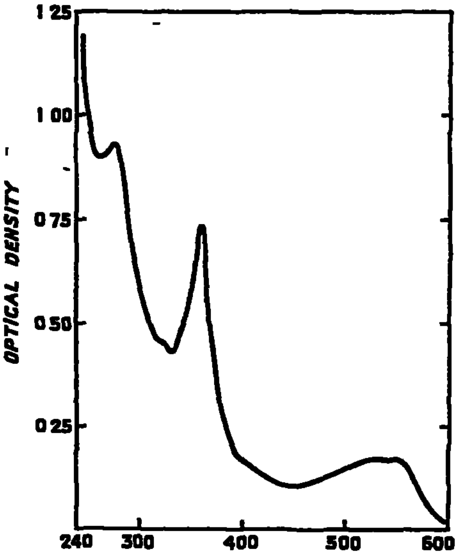

Fig 1—Absorption spectrum of H P P /1

The ultraviolet and visible absorption spectrum of H P P /1 (fig 1) possessed absorption maxima at 277 mμ, 361 mμ, and 550 mμ—i e, in the same positions as those of vitamin B_{12} The maximum at about 277 mμ was appreciably greater than the corresponding peak value for the pure vitamin

Both paper chromatography and paper electrophoresis showed the presence of only one vitamin-B_{12}-peptide Acid hydrolysis of the peptide component by 6N HCl at 100°C for twenty-four hours yielded a mixture of aminoacids, of which the following were identified by paper chromatographic separation and appropriate staining glutamic acid, aspartic acid, glycine, alanine, valine, proline, serine, threonine, arginine, cystine (or cysteine), leucine, isoleucine, phenylalanine, lysine, and histidine Methionine and hydroxyproline were not detected

Alkaline hydrolysis, followed by paper chromatography, established, with specific reagents—e g, Ehrlich's reagent—the presence of the essential amino acid tryptophane

For accuracy in administration of the tiny doses of active complex required, the vitamin content was estimated both spectrophotometrically at 550 mμ as mentioned above and by direct microbiological assay using *Ochromonas malhamensis* as the test organism That the vitamin in H P P /1 was directly assayable by organisms that require the vitamin as a growth factor shows that, according to generally accepted terminology, the vitamin was "free" and not "bound"

Maturation of Megaloblasts

Although it has been shown that folinic acid, folic acid, and vitamin B_{12} plus normal gastric juice bring about the maturation of megaloblasts in vitro, neither crystalline vitamin B_{12} nor gastric juice alone has any such effect (Callender and Lajtha 1951)

An attempt was therefore made to discover the effect of the vitamin B_{12}-peptide complex on megaloblasts in culture The technique was based upon that described by Lajtha (1952), except that Ringer's solution was used instead of Gey's, and it was found that the addition of 50 units of penicillin added to *each tube* reduced the risk of contamination The final concentration of homologous-serum in the culture medium was 80% The

18 HR CULTURES OF MEGALOBLASTIC MARROW IN 80% HOMOLOGOUS SERUM

Case no	Initial count		Cultures in					
			80% serum (8 ml)		80% serum (8 ml)+7 8 µg H P P /1 (vitamin B_{12} 1 µg)		80% serum (8 ml)+1 mg of folic acid	
	Megaloblasts %	Normoblasts %	Megaloblasts %	Normoblasts %	Megaloblasts %	Normoblasts %	Megaloblasts %	Normoblasts %
5	94	6	87	13	55	46	59	41
6	90	10	72	28	35	65	32	68

500 cells were counted on each film

results are given in the accompanying table, which shows that maturation takes place about as rapidly in the presence of vitamin-B_{12}-peptide as with folic acid in eighteen-hour cultures

Clinical Results

Six newly diagnosed cases of pernicious anæmia were treated exclusively with H P P /1 The patients were four males and two females, aged 42–72 A seventh case, which had begun to develop signs of subacute combined degeneration of the cord on treatment with another oral preparation containing intrinsic factor, is described separately below

Pernicious anæmia was diagnosed in every case by a full examination of peripheral blood, a histamine-alcohol test-meal, and biopsy of the sternal marrow (hæmoglobin 100% = 14 8 g per 100 ml)

Reticulocyte-counts were done in each case for at least three days before treatment to exclude the possibility of a coincident spontaneous remission

Dosage

As has been mentioned already, the ratio of peptide to vitamin B_{12} in H P P /1 is 6 8 1 Thus 100 µg of vitamin B_{12} is contained in 780 µg of H P P /1 For the sake of clarity the dose is given below in quantities of H P P /1 with the vitamin-B_{12} content in parentheses At no time was crystalline vitamin B_{12} given either orally or parenterally, except where specifically mentioned in case 7

Broadly speaking, treatment of pernicious anæmia is carried out in two consecutive uninterrupted stages (1) correction of the deficiency of vitamin B_{12}, and (2) maintenance of the patient on a lower dosage Ultimately the success or failure of any preparation will be judged on the second stage, for it has been shown (Blackburn et al 1955, Mooney 1956) that a good initial response to oral therapy is no guarantee of successful maintenance over long periods

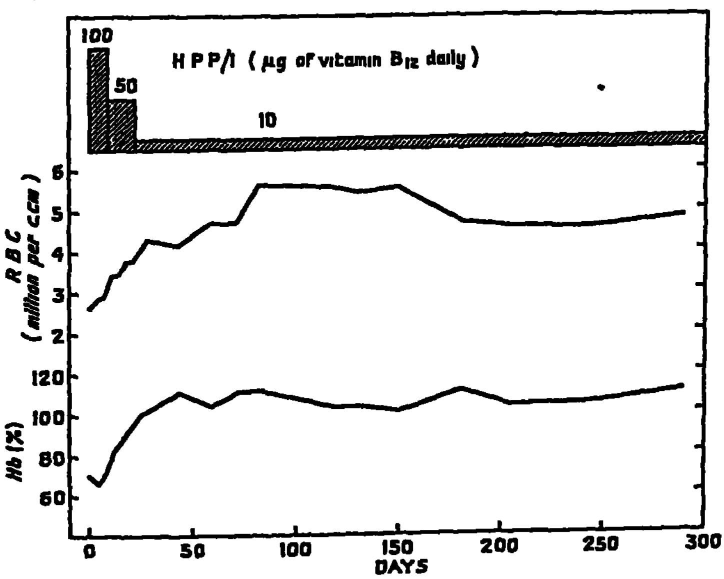

Fig 2—Case 1 (male, aged 44) blood response to oral H P P /1

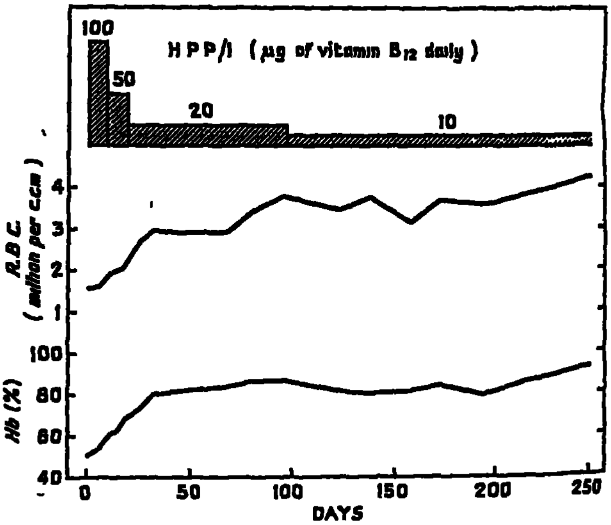

Fig 3—Case 2 (female, aged 72) blood response to oral H.P P /1

Initial dose—As it is generally agreed that the liver contains 1–2 mg of vitamin B_{12} in health, it was decided to give case 1 780 µg of H P P /1 (vitamin B_{12} 100 µg) daily for eight days, and then half that amount for fourteen more days (total dose of vitamin B_{12} 1500 µg) Dosage was varied slightly in subsequent cases but never exceeded this amount in the first three weeks' treatment

Maintenance dose—As already mentioned, Ungley (1952) considered that a daily oral dose of 5–10 µg of crystalline vitamin B_{12} had no detectable effect on the blood-picture Thus, if a patient could be maintained in health within this range of dosage, it would be reasonable to presume that the preparation was effective Accordingly 78 µg of H P P /1 (vitamin B_{12} 10 µg) was given as a daily maintenance dose in each case, except the following

Case 2 received 156 µg of H P P /1 (vitamin B_{12} 20 µg) from the 22nd to the 95th day of treatment, through fear that absorption might be impaired because she was aged 72 After the 95th day this dosage was reduced to 78 µg (vitamin B_{12}, 10 µg), and it has remained at this level up to now (246th day) without deterioration in the blood-picture

Case 3 received no treatment from the 68th to the 130th day, and his blood-picture deteriorated A single dose of 1560 µg of H P P /1

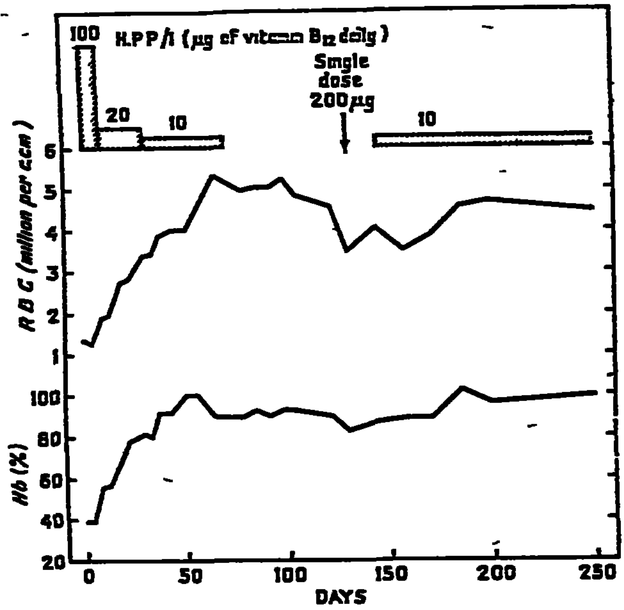

Fig 4—Case 3 (male, aged 62) blood response to oral H.P.P /1

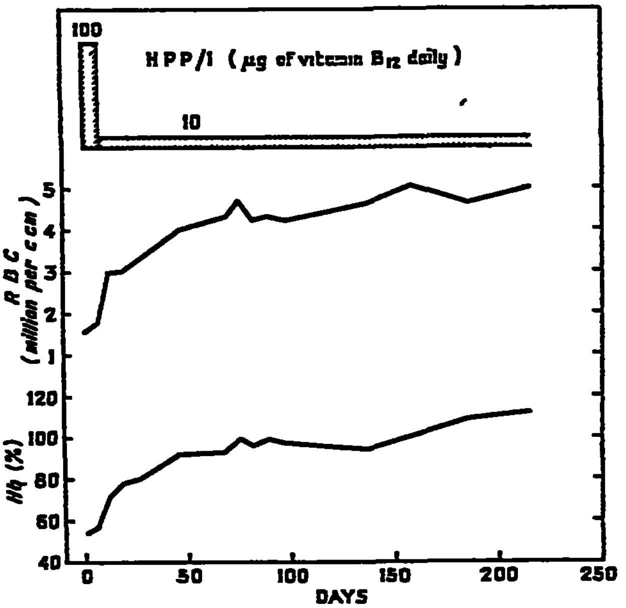

Fig 6—Case 5 (male, aged 42) blood response to oral H.P.P /1

(vitamin B_{12} 200 μg) was given on the 131st day, and from the 145th day up to now (186th day) he has received 78 μg (vitamin B_{12} 10 μg) daily

Case 6 was given weekly instead of daily doses, and from the 74th to the 123rd day she received 312 μg of H.P.P /1 each week (vitamin B_{12} 40 μg) As the blood-picture was suspected to be deteriorating (fig 7), the weekly dose was increased to 546 μg (vitamin B_{12} 70 μg) on the 124th day

Results

There was a good hæmatological and clinical response, which has been maintained in all six cases, for periods ranging from 140 to 290 days (figs 2–7) A reticulocyte crisis with maxima of 11–17% developed at about the end of the first week in every case, and the average daily increases in red cells and hæmoglobin in the first 28 days' treatment were 47,000 per c.mm. and 1·07% respectively No case up to now has developed signs either of cord deterioration or of iron deficiency

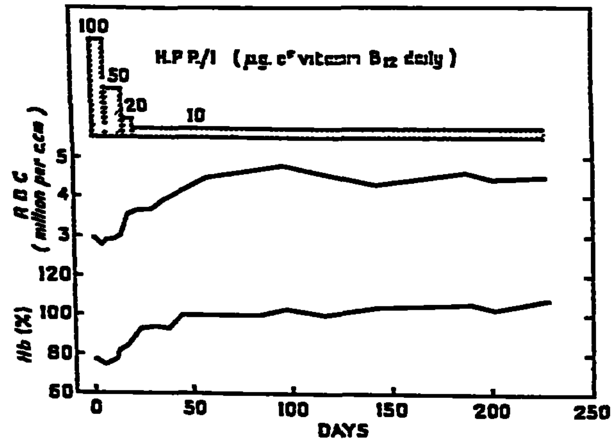

Fig 5—Case 4 (male aged 64) blood response to oral H.P.P /1

Case 7 —A woman, aged 52, had been treated with another oral preparation ('Bifacton') since pernicious anæmia had been diagnosed sixteen months previously She had responded well and had been maintained in health during this time but then began to experience difficulty in both standing up and walking, also she noticed numbness of her feet. On examination vibration sense was absent over both ankles, her knee-jerks and ankle-jerks were sluggish and her plantar reflexes equivocal. Sensation to cotton-wool was absent on the soles of both feet. Her red cells numbered 4,300,000 per c.mm. and her hæmoglobin was 94% Early subacute combined degeneration of the cord was diagnosed, and it was decided to treat her with the oral peptide complex H.P.P /1 in larger doses

Treatment.—For the first three weeks she received 2340 μg of H.P.P /1 (vitamin B_{12} 300 μg) daily and thereafter 1560 μg of H.P.P /1 (vitamin B_{12} 200 μg) daily for eight more weeks Oral treatment then had to be abandoned owing to shortage of experimental material, and the patient was given 1000 μg of parenteral crystalline vitamin B_{12} weekly

Progress—During the eleven weeks' oral therapy an unequivocal subjective improvement took place. Her walking improved, and her sensory symptoms diminished Vibration sense returned to all her malleoli except the right internal, and her reflexes showed no detectable change either way This improvement has been maintained on parenteral treatment. During twenty-four weeks' oral and parenteral treatment, her blood-count has remained essentially unaltered, and her latest red-cell count is 4,700,000 and her hæmoglobin 97%

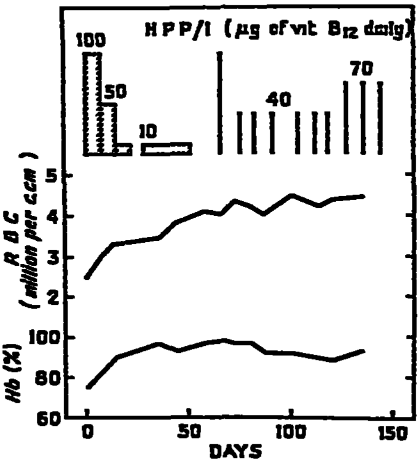

Fig 7—Case 6 (female, aged 62) blood response to oral H.P.P /1

Discussion

The current view on the ætiology of pernicious anæmia is that the absorption of the extrinsic factor (crystalline vitamin B_{12}) is facilitated by combination with the intrinsic factor Furthermore, an additional or third factor is required (Glass et al 1954) to bring about the absorption of such a large molecule in the small intestine

As crystalline vitamin B_{12} does not exist in nature but is found mostly in the "bound" form, then, if these views are correct, at some stage the crystalline vitamin must be completely detached from this protein of high molecular weight This splitting is difficult to bring about in the laboratory (Lester-Smith 1948), and whether it could occur in normal digestion in the stomach is doubtful We are certainly not aware of any reports that crystalline vitamin B_{12} has been produced in vitro from gastric secretions alone

Likewise there is no laboratory evidence that the crystalline vitamin, if it occurs as such in the stomach, combines with a specific intrinsic factor, for none has yet been isolated This does not mean that the vitamin cannot combine with the mucoproteins found in the stomach On the contrary, there is evidence (Hall 1950, Gregory and Holdsworth 1953, Wijmenga et al 1954b) that the crystalline form of the vitamin will combine readily with various proteins

There remains too the question how this non-dialysable complex is transported across the intestinal wall The third factor of Glass et al (1954) is hardly a satisfactory explanation, because it has not yet been isolated Thus, if present concepts are correct, stomach juices must be capable of freeing vitamin B_{12} from all protein adherents, furthermore, two factors—the intrinsic and the third factors—must also exist, neither of which has yet been isolated or identified

If the currently accepted ideas are correct, it should be possible to treat patients successfully by giving them orally a preparation of intrinsic factor together with a relatively small dose (say 30–45 µg) of vitamin B_{12} Although several such preparations of vitamin B_{12} and intrinsic factor have been marketed, the results have been disappointing (Blackburn et al 1955, Schwartz et al 1957) However, for reasons mentioned already, we believe that the true cause of the failure lies in something even more fundamental than this—namely, that the disease is due to a failure of simple proteolysis in the stomach In suggesting this we are largely returning to the original conception of the nature of pernicious anæmia proposed by Castle et al, who as long ago as 1930 said that it was "due to a virtual deficiency brought about, even in the presence of a diet adequate for the normal individual, by defective gastric digestion of protein as a result of the achylia gastrica"

This idea was largely discarded when it was found impossible to obtain a remission in the disease by giving pepsin and hydrochloric acid (Wilkinson 1930, Castle et al 1930), and its place has gradually been taken by the modern conception of an actual synthesis of the two factors—intrinsic and extrinsic—to form the hæmopoietic principle The isolation of crystalline vitamin B_{12} (Lester-Smith 1948, Rickes et al 1948) and its equation with the extrinsic factor (Castle 1953, Berk et al 1948) have strengthened this later view Nevertheless, as the search for the intrinsic factor has so far been unsuccessful, it cannot yet be claimed that this modern concept of the nature of pernicious anæmia is proven Indeed, from the results reported here it appears that Castle's original views may still be correct, for we have found it possible to bring about a remission in this disease by the agency of vitamin-B_{12}-peptide complex

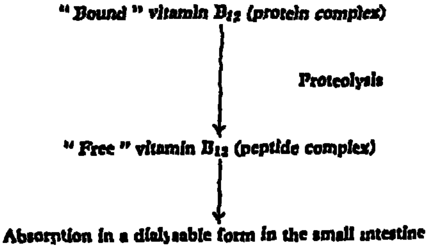
As the naturally occurring vitamin is mostly bound to protein, it seems to be an inescapable conclusion that degradation of protein must, at some stage, take place in the normal assimilation of vitamin B_{12} from food Furthermore, as no animal intrinsic factor is involved in the preparation of H P P /1 at any stage, doubt must be cast not only on its supposed rôle in pernicious anæmia but also on its existence

Before returning to Castle's original theory and restating it in the light of the results reported here, we must make clear the distinction between the confused terms "free", "bound", and crystalline vitamin B_{12}

To say that the vitamin is in the "free" form usually means that it is utilisable by those microorganisms which require it as a growth factor, and in this state it is presumably capable of diffusing through the cell wall of the organism Although the crystalline form is always "free" in this sense, the terms "crystalline" and "free" are not synonymous, nor are estimations of "free" and crystalline vitamin B_{12} in a given sample necessarily identical (Ford 1953, Hutner et al 1956) It is even possible to obtain variable estimations of "free" vitamin-B_{12} content—depending on the type of organism used—on a sample in which it is known that the amount of crystalline vitamin is constant. *Escherichia coli*, for example, gives consistently higher values of "free" vitamin-B_{12} content (Ford 1953) than does *Euglena gracilis* or *Ochromonas malhamensis* (Hutner et al 1956) As non-crystalline "free" forms of the vitamin have some peptide attached, probably this plays a variable part in the assimilation and/or utilisation of the vitamin by the test organisms

The term "bound" vitamin B_{12} means that, in this form, it is non-assimilable and non-utilisable by microorganisms It is readily converted into its "free" counterpart either by heating in an acid medium for fifteen minutes at 100°C or by proteolytic digestion Thus the conversion of "bound" into "free" vitamin B_{12} appears to entail a reduction in molecular size of the protein attached to the vitamin

Applying these terms, Castle's (1930) original theory might be stated anew as follows



"Bound" vitamin B12 (protein complex)
Proteolysis
"Free" vitamin B12 (peptide complex)
Absorption in a dialysable form in the small intestine

In other words, we believe that the complex containing a protein of high molecular weight, in which form vitamin B_{12} usually occurs in nature, is converted in the stomach into a complex containing a peptide of low molecular weight which is dialysable and assimilable by micro-organisms On this theory, extrinsic and intrinsic factors are no longer necessary, nor is the third factor of Glass, because this "free" form of the vitamin will be of a suitable size for simple absorption in the small intestine

From the clinical results presented here it is clear that patients with pernicious anæmia can be adequately maintained on oral daily doses of 10 µg of vitamin B_{12} when the latter is combined as a peptide complex derived from fermentation If these results mean anything, it must be that an intrinsic factor from animal sources, whether homologous (human) or heterologous (hog, &c) is not essential for absorption of the vitamin We believe, therefore, that intrinsic factor, as currently understood, has no real existence per se, and that the fundamental process preceding absorption of vitamin B_{12} is simply one of normal degradation or digestion of animal protein

Despite the lack of direct proof as yet, this conception of impaired proteolysis as the cause of pernicious anæmia seems to be more rational and physiological than that currently held whereby both degradation and synthesis are alleged to occur simultaneously in the same organ Furthermore, as vitamin B_{12} is usually found in the "bound" form in nature, it seems unlikely that it should be rendered "free" only to be "bound" again before absorption

In any case it is also clear from the present clinical results that H P P /1 is the most effective oral preparation yet described, because the ratio of peptide to vitamin is only 6 8 1 In other oral preparations the attached or admixed proteinaceous material (so-called "intrinsic factor") has never been less than 200 parts to 1, and usually the ratio is higher Furthermore, this preparation matured megaloblasts in vitro at about the same speed as did folic acid

Since crystalline vitamin B_{12} alone cannot bring about maturation, vitamin B_{12} seems to be more acceptable nutritionally for maturation when combined as a peptide complex and is, in this form, a closer approximation to the anti-pernicious-anæmia factor of liver than is the purified vitamin In this connection Murphy's (1954) caution that "further critical study is necessary before vitamin B_{12} is accepted as a complete substitute for either whole liver or liver extracts" is not without significance Indeed it seems likely that the vitamin might not only be absorbed but also be utilised in some similar form to this natural preparation H P P /1 Finally, we do not, on the evidence at present available, suggest that all "free" forms of the vitamin—i e, all peptide complexes—are necessarily effective clinically, but, from the results of more recent work to be published later, it appears that all active forms are probably "free"

Summary

A brief outline is given of existing theories of the causation and treatment of pernicious (Addisonian) anæmia,

Some of these have been responsible for the pursuit of intrinsic-factor preparations of high molecular weight which have not proved especially efficacious

No hypothesis so far has been able to completely and satisfactorily explain the mode of transport of vitamin B_{12} into the blood-stream

A new hypothesis is put forward that the orally active form of the vitamin is a peptide complex

Such a vitamin-B_{12}-peptide has been isolated from a fermentation of streptomyces, and it has been shown clinically to be the most effective oral preparation yet available

It is postulated that this active complex could be produced in the stomach by simple proteolysis, and that the intrinsic factor probably does not exist

It is a pleasure to acknowledge the ready cooperation we have received from Dr E T Baker-Bates and Dr G M S Ryan, who kindly allowed us to use some of their cases We thank the directors of the Distillers Co (Biochemicals) Ltd for permission to publish certain details of the method of preparation of H P P /1

THE two principal current methods of controlling severe tetanus convulsions are the use of sedative drugs and neuromuscular block with artificial respiration The latter method is only suitable for special centres since the technical facilities required are considerable, moreover it has yet to be conclusively demonstrated that this method is a therapeutic advance It may ultimately prove essential for the more severe cases, but most cases of tetanus in the world will continue to be treated by simple sedation methods because the disease tends to be common where medical services are underdeveloped

We have been impressed by the prominence of polypharmacy in published reports of tetanus and by the absence of properly designed clinical trials by which individual drugs might be evaluated We compare here two sedation methods of treatment which were given concurrently, patients being allocated at random to one of two treatment groups

Design of Clinical Trial

Chlorpromazine was compared with barbiturates, and the trial was conducted on African and Indian patients admitted to the same unit at King Edward VIII Hospital, Durban

When the clinical diagnosis had been made, the patient was allocated to a treatment group by opening the next of a series of envelopes containing cards randomised between these two treatments by Dr D D Reid, of the statistical research department, London School of Hygiene and Tropical Medicine

To make sure that any differences between the two groups were due to the drug treatment only, all other treatment was standardised as far as possible Patients were also divided into two main groups, neonates and non-neonates

Standardised Treatment

Non-neonates

Procedure on admission—The patient was put on a bed and sedated with the appropriate drug, given intramuscularly or intravenously according to the severity of the tetanus, and the test dose of antitoxin was administered He was then left alone for thirty minutes, after which time he was undressed, the main doses of antitoxin were given, the wound was tended, and any necessary nursing procedures were performed

Tetanus antitoxin—All the patients received a subcutaneous test dose of 800 I U of tetanus antitoxin Thirty minutes later 100,000 I U was given intramuscularly, and thirty minutes after that all the patients aged more than 10 years were given 100,000 I U intravenously

Chemotherapy—All the patients who were aged more than 10 years were given 600,000 units, and those aged less than 10 years 300,000 units, of procaine penicillin twice daily intramuscularly during the course of the disease If clinical pneumonia developed, soluble penicillin 500,000 units was given four-hourly to patients aged more than 10 years, and the same dosage six-hourly to those aged less than 10 years

Feeding—At first a nasal or an oral stomach-tube was passed on all the patients, but later this was not done until the patient had shown himself unable to swallow Feeding was with a suitably fortified egg-and-milk mixture Intravenous feeding was undertaken when tube-feeding failed for any reason, or if the patient was dehydrated

Nursing procedures were carried out as far as possible an hour after a sedative injection

The wound was treated as it would have been if the patient had not got tetanus

Neonates

The procedure on admission was to sedate the patient as for the non-neonates No test dose of antitoxin was used, 50,000 I U was injected intramuscularly

Benethamine penicillin 300,000 units was injected intramuscularly every third day If clinical pneumonia developed this was changed to 500,000 units of soluble penicillin six-hourly

The umbilicus was cleaned with hydrogen peroxide, and merthiolate was applied to it

Feeding was by nasal or by oral tube, or intravenously if this failed At the beginning of the trial expressed breast-milk, or substitute, was given four-hourly, but this was altered to half the amount two-hourly because regurgitation developed, with its attendant risk of aspiration pneumonia Hartmann's solution was given through the stomach-tube if the child appeared dehydrated The infants were nursed with the foot of the cot raised so that bronchial and oral secretions would tend to flow out

Drug Dosage

This varied at first but was soon standardised as follows

Barbiturates

Non-neonates—Phenobarbitone sodium was the standard treatment An adult with typical moderately severe tetanus received about 200 mg intramuscularly three- to six-hourly at first, according to the frequency of convulsions When sedation was needed urgently, amylobarbitone sodium 0 25–1 00 g was given either intramuscularly or intravenously

Neonates were similarly treated with intramuscular phenobarbitone sodium 60 mg six- to eight-hourly at first, with longer intervals after the first two or three days because of the cumulative action of the drug

Chlorpromazine

Non-neonates—An adult with typical moderately severe tetanus received 100–150 mg intramuscularly four- to six hourly A total of 1 g in twenty-four hours was seldom exceeded Similar doses were given intravenously where control of convulsions was urgent At first, when patients appeared mentally distressed, promethazine, chemically close to chlorpromazine, was used in an attempt to increase sedation It was ineffective for this purpose and was soon abandoned

Neonates were similarly treated, regard being paid to their age, 20–25 mg being given four-hourly initially A total of 220 mg in twenty-four hours was seldom exceeded

In all the cases drugs were given orally only during the stage of recovery

Assessment of Severity

The severity of the tetanus was classified as follows

Mild rigidity but no reflex spasms
Moderate reflex spasms present but either mild or infrequent
Severe frequent severe reflex spasms

Results

Tables I and II compared the two treatment groups Table III gives the mortality figures Table IV gives the complication-rates and feeding routes Table V gives the principal prognostic criteria of tetanus, the period of onset—the time from the first symptom to the first generalised reflex spasm (Cole 1940)—and the incubation period

Discussion

Choice of Drugs

Barbiturates were chosen because they are well known to arrest tetanus convulsions although often at the price of unconsciousness and respiratory depression

Chlorpromazine was chosen because it was, at the time of the trial, the most potent of a range of drugs assayed on local tetanus in rabbits (D R Laurence and R A Webster, unpublished) In addition it had been found possible to arrest clinical tetanus spasms by its sole use (Kelly and Laurence 1956, Laurence 1957)

TABLE I—COMPARISON OF GROUPS, NON-NEONATES

Clinical sepsis present on admission	13	17

Division of Patients

Because of the high mortality-rate anticipated and feeding problems, neonates were given a modified standard treatment and the results assessed separately from the non-neontal patients. There were not enough children to make it useful to separate them as a special group.

Procedure on Admission

Immediate sedation followed by a period of quietude was considered essential so that such necessary procedures as the main antitoxin doses and tending the wound would provoke severe convulsions.

Antitoxin Dosage

This was standardised at a high level so that the same dose would be suitable for even the most severe cases. One patient, who had trodden on a nail, was found post mortem to have, deep to the tendons on the sole of his foot, an abscess which had given no signs of its presence during life. Since it is possible that this was a source of huge amounts of toxin, the antitoxin administered may have been inadequate in this case. No hypersensitivity reactions occurred.

TABLE III—DEATHS

—	Chlorpromazine treated	Barbiturate treated
Non-neonates		
No of cases	23	21
No of deaths	10 (*43%*)	11 (*52%*)
Deaths among patients surviving more than 24 hr in hospital	8 (*38%*)	8 (*44%*)
Neonates		
No of cases	14	17
No of deaths	13 (*93%*)	12 (*71%*)
Deaths among patients surviving more than 24 hr in hospital	10 (*91%*)	11 (*69%*)

Feeding

Previous experience had taught us that it is better to pass a stomach-tube unnecessarily than to leave it too late. Once difficulty in swallowing has developed, passage of the tube may soon become very difficult indeed, the disturbance of the patient is tremendous, and the tube is liable to enter the trachea. The ability of half of the non-neonates treated with chlorpromazine to swallow successfully (table IV) was striking, and we attribute this to the drug. Of the barbiturate group 30% required intravenous feeding because a stomach-tube could not be passed; this contrasts with the chlorpromazine group, where none needed intravenous therapy because of failure to pass a tube. All the neonates were fed by stomach-tube except 1 in the barbiturate group, who was fed intravenously because a tube could not be passed.

Bronchial and Oral Secretions

These were encouraged to flow out by nursing all the patients tilted head down. Oral suction was occasionally used, tracheal suction never.

General Nursing

Disturbance of the patient was avoided as much as possible. A specially allotted nurse was usually available, but she often had to care for as many as four seriously ill patients at a time. At other times this was done by an untrained nursing aide.

Oxygen

Oxygen was not used in the non-neonates, because cyanosis was not a feature except immediately after convulsions, and it never persisted after respiration had been re-established. Attempts were made to give oxygen to the neonates by nasal tube, but this provoked such vigorous spasms that it was abandoned. Oxygen tents and incubators were not available, and it is uncertain whether they would have been useful.

TABLE IV—COMPLICATIONS AND FEEDING

—	Chlorpromazine treated		Barbiturate treated	
	Survived	Died	Survived	Died

Oral	0	0	0	0
Tube	1	12	5	11
Intravenous	0	0	0	1
Not fed (died too soon)	0	1	0	0

Chlorpromazine

This was usually given intramuscularly. It is intensely irritant and, although this was not a problem in the non-neonates, the neonates developed extensive induration of their muscles, which must have been painful and tended to provoke spasms. Histological study after death showed necrosis of muscle at the injection sites. An attempt was made to mitigate this by diluting the solution (25 mg. or 50 mg. per ml.) with at least its own volume of saline solution, but this probably made no difference.

TABLE V—PRINCIPAL PROGNOSTIC CRITERIA

Treatment group	Average period of onset (hr)	Average incubation period (days)
Non-neonates		
Chlorpromazine		
Deaths	23	15 (6/10)*
Survivals	41	15 (11/13)*
Barbiturates		
Deaths	13	11 (9/11)*
Survivals	48	10 (8/10)*
Neonates		
Chlorpromazine		
Deaths	9	6
Survivals	27	8
Barbiturates		
Deaths	10	5
Survivals	38	6

* These figures indicate the number of cases in which it was known—i.e., 6/10 = 6 out of 10 cases.

In neonates the incubation period was presumed to start at birth.

In 1 case very severe generalised convulsions were not arrested by 500 mg of chlorpromazine given intravenously In all the other cases the convulsions were controlled by smaller doses and were not usually thought to be the primary cause of death It is difficult to decide exactly what causes death in tetanus
